ABSTRACT

We report initial results from the far-infrared fine structure line observations of a sample of 44 local starbursters, Seyfert galaxies, and infrared luminous galaxies obtained with the PACS spectrometer on board Herschel. We show that the ratio between the far-infrared luminosity and the molecular gas mass, $L_{\text{FIR}}/M_{\text{H}_2}$, is a much better proxy for the relative brightness of the far-infrared lines than $L_{\text{FIR}}$ alone. Galaxies with high $L_{\text{FIR}}/M_{\text{H}_2}$ ratios tend to have weaker fine structure lines relative to their far-infrared continuum than galaxies with $L_{\text{FIR}}/M_{\text{H}_2} \lesssim 80 \, L_{\odot} \, M_{\odot}^{-1}$. A deficit of the $[\text{C}\,\text{ii}]$ 158 $\mu$m line relative to $L_{\text{FIR}}$ was previously found with the Infrared Space Observatory, but now we show for the first time that this is a general aspect of all far-infrared fine structure lines, regardless of their origin in the ionized or neutral phase of the interstellar medium. The $L_{\text{FIR}}/M_{\text{H}_2}$ value where these line deficits start to manifest is similar to the limit that separates between the two modes of star formation recently found in galaxies on the basis of studies of their gas–star formation relations. Our finding that the properties of the interstellar medium are also significantly different in these regimes provides independent support for the different star-forming relations in normal disk galaxies and major merger systems. We use the spectral synthesis code Cloudy to model the emission of the lines. The expected increase of the ionization parameter with $L_{\text{FIR}}/M_{\text{H}_2}$ can simultaneously explain the line deficits in the $[\text{C}\,\text{ii}]$, $[\text{N}\,\text{ii}]$, and $[\text{O}\,\text{ii}]$ lines.

Key words: galaxies: evolution – galaxies: ISM – galaxies: starburst – infrared: ISM

1. INTRODUCTION

During most of their life, galaxies form stars at a relatively low rate regulated by the total amount of molecular gas mass available (e.g., Bigiel et al.2008). This phase of semi-continuous star formation can be interrupted by short periods of violent star formation, normally associated with the merging of massive galaxies. In mergers, most of the molecular gas is compressed on a scale of a few hundred parsecs to a few kiloparsecs around the nuclei and, by a mechanism not yet well understood, forms stars with high efficiency (Sanders & Mirabel 1996). These episodes of high efficiency (Sanders & Mirabel 1996) are also significantly different in these regimes provides independent support for the different star-forming relations

$\mu$...
2. OBSERVATIONS AND DATA REDUCTION

The observations discussed in this Letter are part of the Herschel guaranteed time key program SHINING (PI: E. Sturm), devoted to study the far-infrared properties of a sample of more than 100 galaxies, that includes local starbursts, Seyfert galaxies, low-metallicity systems, and infrared luminous galaxies at low and high redshift. Here, we present the fine structure line data for the first 44 galaxies: 16 Seyferts (NGC 1068 and Cen A, among others), 5 H ii galaxies (e.g., M 82, M 83, NGC 253), 21 LIRGs and ULIRGs (e.g., NGC 4418, Arp 220, Mrk 231), and 2 high-redshift galaxies (IRAS F10214+4724 and MIPS J142824.0+352619).

The observations were obtained with the PACS far-infrared spectrometer (Poglitsch et al. 2010) between 2009 October and 2010 December. We observed the three PDR lines [C ii] 158 μm, [O i] 145 μm, and [O i] 63 μm, and the four H ii lines [N ii] 122 μm, [O iii] 88 μm, [N iii] 57 μm, and [O ii] 52 μm in most galaxies, with some exceptions due to data acquisition problems and scheduling constraints. The rest-frame wavelength of the [O ii] 52 μm line is at the low sensitivity edge of the PACS range and was observed only in the high-redshift galaxies (see Sturm et al. 2010).

The data were reduced using the standard PACS reduction and calibration pipeline included in HIPE 5.0. However, for the final calibration we normalized the spectra to the telescope flux and recalibrated it with a reference telescope spectrum obtained from dedicated Neptune observations. For unresolved sources, this method gives excellent agreement (differences ≤15%) between the IRAS 60 μm and 100 μm flux densities and those measured with PACS when extrapolating from the continuum close to the lines.

Most of the targeted lines were detected. For the extended galaxies, we integrated the line fluxes and FIR continuum within the 47″ × 47″ PACS field of view. The detailed spatial information for these sources will be discussed in a future paper.

3. RESULTS

3.1. The [C ii] Line Deficit

The well-known [C ii] line deficit in infrared luminous galaxies is shown in Figure 1(a). Together with the PACS data, we have plotted a comparison sample composed of all galaxies observed with ISO (Negishi et al. 2001; Malhotra et al. 2001; Luhman et al. 2003; Braucher et al. 2008). High-redshift galaxies (z = 1.1–6.4) with [C ii] observations are also included (Maiolino et al. 2009; Hailey-Dunsheath et al. 2010; Ivison et al. 2010; Wagg et al. 2010; Stacey et al. 2010, and references therein). The average [C ii]/FIR ratio is approximately constant in galaxies with low infrared luminosities, but starts to decrease at $L_{\text{FIR}} \sim 10^{11} L_\odot$. At the same time, the scatter in the ratio increases by almost a factor of two: some high-redshift galaxies do not show a [C ii] deficit, even if their far-infrared luminosities are higher than $10^{12} L_\odot$, and the source with the lowest [C ii]/FIR ratio is NGC 4418, a galaxy with $L_{\text{FIR}} \simeq 10^{11} L_\odot$.

The scatter at high $L_{\text{FIR}}$ can be reduced by a factor ~1.5 if $L_{\text{FIR}}/M_{\text{H}_2}$ is used7 instead of $L_{\text{FIR}}$ (Figure 1(b)), presumably because this ratio is more closely related to the properties of the clouds (gas density and dust temperature) than $L_{\text{FIR}}$ alone (e.g., Gao & Solomon 2004). Galaxies with similar $L_{\text{FIR}}$ luminosities can have very different $L_{\text{FIR}}/M_{\text{H}_2}$ ratios and the excitation conditions in their interstellar medium will also differ (González-Alfonso et al. 2008). With this new representation, high-redshift galaxies overlap with their low-redshift counterparts and NGC 4418 is shifted to the right of the figure due to its relatively low molecular gas content. A similar result was obtained by Malhotra et al. (2001) using the IRAS S60/μm/S100/μm color in a smaller sample of local galaxies observed with ISO.

3.2. A General Far-infrared Line Deficit

Figure 2 shows the line to FIR continuum ratio against $L_{\text{FIR}}/M_{\text{H}_2}$ for all the fine structure lines observed with PACS.

---

7 $M_{\text{H}_2}$ was estimated using previously published CO observations of the galaxies. We used a $X_{\text{CO}}$ conversion factor that is a continuous function of the IRAS S60/μm/S100/μm color in a way that produces adequate values for Milky Way type galaxies (~4 $M_\odot$ L$^{-1}$, with L' in units of K km s$^{-1}$ pc$^2$) and ULIRGs (~0.8 $M_\odot$ L$^{-1}$). Some high-redshift galaxies did not have enough photometric data points to estimate their rest-frame S60/μm/S100/μm color; $X_{\text{CO}} = 2 M_\odot$ L$^{-1}$ was used in those cases.
Our main result is that we now find line deficits in both the PDR and the H II lines. All the line to FIR ratios start to decrease at $L_{\text{FIR}}/M_{\text{H}_2} \sim 80 L_\odot M_\odot^{-1}$. This result also does not seem to depend on the optical activity classification of the galaxies. We note, however, that the integrated emission of the [O I] and [O III] lines in some Seyfert galaxies might have a significant contribution from X-ray dominated regions close to the active galactic nucleus (AGN; e.g., Maloney et al. 1996).

The [O I] 63 $\mu$m line was detected in absorption at some velocities in NGC 4418, Arp 220, and IRAS 17208-0014. The [O I] 63 $\mu$m/FIR ratios used in Figure 2 correspond to the emission components only and should be regarded as lower limits. This will reduce the deficit observed for this line to some extent, but will not eliminate it, as other galaxies (e.g., Mrk 231; Fischer et al. 2010) with no clear absorption features in their line profiles do still have lower [O I] 63 $\mu$m/FIR ratios than galaxies with $L_{\text{FIR}}/M_{\text{H}_2} < 80 L_\odot M_\odot^{-1}$. The [O I] 145 $\mu$m line is less likely to be affected by this kind of absorption and also shows a deficit at high $L_{\text{FIR}}/M_{\text{H}_2}$. There is no sign of absorption by foreground material in the other fine structure lines at the current PACS velocity resolution ($\sim 100$–250 km s$^{-1}$).

In summary, our observations show that the line to FIR continuum ratio drops by a factor of 3 to 10 above $L_{\text{FIR}}/M_{\text{H}_2} \sim 80 L_\odot M_\odot^{-1}$ in all the far-infrared fine structure lines we have observed. This drop seems to be a universal feature of galaxies at different redshifts and with different optical activity classifications. Neutral and ionized gas tracers are affected, as are lines with different rest-frame wavelengths, intrinsic optical depths, and critical densities. This eliminates most of the proposed explanations for the [C II] deficit, leaving the dependence on the $L_{\text{FIR}}/M_{\text{H}_2}$ ratio as the most plausible dominant factor driving the deficits. We have assumed in this Letter that $L_{\text{FIR}}$ is mostly due to star formation. This might not be true for some galaxies like Mrk 231, but even an AGN contribution of 50% to $L_{\text{FIR}}$ will fall short of explaining the factor of 10 decrease in some of the line to FIR ratios.

In the next section, we show with quantitative modeling that high ionization parameters can indeed account for most of the observed line deficits. The key factor is that in dusty star-forming regions the fraction of luminosity absorbed by dust particles in ionized gas as well as neutral gas increases with $U$.

### 4. COMBINED H II AND PDR LINE MODELS

Abel et al. (2009) used the spectral synthesis code Cloudy (Ferland et al. 1998) to model the [C II]/FIR ratio in clouds exposed to different radiation fields. They found that they could reproduce the [C II] line deficits observed in some local LIRGs and ULIRGs, as well as their warmer IRAS $S_{60 \mu m}/S_{100 \mu m}$ colors, by increasing the value of the ionization parameter at the surface of the clouds. As $U$ increases, the H II region is extended to higher $A_V$ into the cloud. As a result, a larger fraction of the UV photons are absorbed by the dust in the ionized region and reemitted in the form of infrared emission. The net effect is that the fraction of UV photons available to ionize and excite the gas is reduced at high $U$, decreasing the relative intensity of the fine structure lines compared to the FIR continuum (see also Voit 1992). Since the number of UV photons per dust particle increases with $U$, the dust temperature (and the $S_{60 \mu m}/S_{100 \mu m}$ color) increases.

We have extended the analysis in Abel et al. (2009) to include all the fine structure lines observed with PACS. We used Cloudy to simultaneously calculate the emission from the molecular, neutral, and ionized gas assuming pressure equilibrium in the clouds. The ionizing source was represented by a non-LTE CoStar stellar atmosphere (Schaerer & de Koter 1997) with $T_\star = 36,000$ K, and the calculations were stopped at $A_V = 100$ mag...
the only property that varies as important. This may indicate that the ionization parameter is not the effect of the dust opacity on the formation of the lines is less. Lines are produced closer to the ionizing source, where the hydrogen densities \( \sim L^2 \) of magnitude.

\[ \text{log n_H \ [cm^{-3}]} \]

Figure 3. Cloudy model predictions for the observed line to FIR continuum ratios as a function of the hydrogen density and the ionization parameter at the illuminated face of the cloud. Red (gray) areas indicate the approximate range of values in the line to FIR continuum ratios observed in galaxies with \( L_{\text{FIR}}/M_{\text{HI}} \geq 80 L_\odot/M_\odot^{-1} \) (<80 \( L_\odot/M_\odot^{-1} \)). The dashed contour indicates the values of the ionization parameter and hydrogen density that can simultaneously explain all the line to FIR ratios in galaxies with \( L_{\text{FIR}}/M_{\text{HI}} < 80 L_\odot/M_\odot^{-1} \). The arrows show the changes to the line to continuum ratios when the ionization parameter is increased by an order of magnitude. (A color version of this figure is available in the online journal.)

\( (N_H = 2 \times 10^{23} \text{ cm}^{-2} \) for \( A_V/N_H = 5 \times 10^{-22} \text{ mag cm}^{-2} \). To facilitate the comparison with previous studies (Kaufman et al. 1999; Abel et al. 2009), we used the gas-phase elemental abundances from Savage & Sembach (1996): \( C/H = 1.4 \times 10^{-4}, O/H = 3.2 \times 10^{-4}, \) and \( N/H = 7.9 \times 10^{-5} \). In our model, the SED of the ionization source is fixed. Thus, for a given density, an increase of the ionization parameter results in a proportional increase in the number of UV photons at all energies.

In Figure 3, we show the model predictions for the line ratios represented in Figure 2. Models with \( U \sim 10^{-3} \) to \( 10^{-2.5} \) and hydrogen densities \( \sim 10^{1.5} - 10^{3} \) \( \text{ cm}^{-3} \) can simultaneously explain the average line to FIR ratios measured in galaxies with low \( L_{\text{FIR}}/M_{\text{HI}} \) values. The observed [C II], [N II], and [O I] line deficits in galaxies with \( L_{\text{FIR}}/M_{\text{HI}} > 80 L_\odot M_\odot^{-1} \) can be easily understood if their ionization parameters are at least an order of magnitude higher, consistent with the idea that the ionization parameter is approximately proportional to \( L_{\text{FIR}}/M_{\text{HI}} \). However, we cannot explain with this particular model the observed line deficits in the [O III] and [N II] high ionization lines. These lines are produced closer to the ionizing source, where the effect of the dust opacity on the formation of the lines is less important. This may indicate that the ionization parameter is not the only property that varies as \( L_{\text{FIR}}/M_{\text{HI}} \) increases. In future papers we will explore the full parameter space in these models, varying the ionization source (SED), the stopping criteria, and the metallicity of the gas. We will also study the possibility of multiple components contributing to the global far-infrared spectrum of these galaxies, including partial covering of the high ionization regions (e.g., Fischer et al. 2010).

5. DISCUSSION AND CONCLUSIONS

As discussed in the introduction, galaxies can experience short periods of intense star formation, normally associated with the merging of massive galaxies, in which the molecular gas is transformed into stars with high efficiency. A good way to investigate this enhancement of the star formation efficiency is to study the relation between the molecular gas surface density, \( \Sigma_{\text{HI}} \), and the star formation rate surface density, \( \Sigma_{\text{SFR}} \). Recent studies of the global infrared continuum and molecular gas properties of galaxies in the local and high-redshift universe suggest that, independent of redshift, luminous mergers and non-interacting or weakly interacting star-forming galaxies follow two separate Kennicutt–Schmidt relations (\( \Sigma_{\text{SFR}} \propto \Sigma_{\text{HI}}^{1-1.2} \), but different normalizations (Genzel et al. 2010; Daddi et al. 2010). The explanation for this offset in the star formation relations is still not clear, but it may indicate that, in addition to \( \Sigma_{\text{HI}} \), other galaxy properties, like the dynamical timescale, may play a significant role regulating the star formation efficiency of the gas.

The \( L_{\text{FIR}}/M_{\text{HI}} \) value that separates galaxies into these two types of star formation (\( \sim 100 L_\odot M_\odot^{-1} \)) is remarkably similar to the point where we start to find a decline in the fine structure line to FIR ratios. This indicates that the average properties of the neutral and ionized gas are significantly different in these galaxies, broadly consistent with the scenario of a highly compressed more efficient star formation, creating largely enhanced ionization parameters that manifest themselves in lower line to continuum ratios. Our detection of a universal drop of the line to continuum ratio at about the same \( L_{\text{FIR}}/M_{\text{HI}} \) value where Genzel et al. (2010) and Daddi et al. (2010) claim a transition to a more efficient star formation mode gives in turn credence to this interpretation.

In the next two years Herschel will increase the number of galaxies with fine structure line observations in the far-infrared, especially in objects with high \( L_{\text{FIR}}/M_{\text{HI}} \). The detailed study of the line ratios, combined with the use of spectral
synthesis codes like Cloudy, will provide valuable information about the ionizing sources, possible AGN contribution to \( L_{\text{FIR}} \), far-infrared optical depth, and the physical properties and metallicity of the gas. This information will be critical to understand the driving mechanisms involved in these modes of star formation.

We thank the referee, Greg Bothun, for his comments and suggestions, which helped to clarify the Letter. PACS has been developed by a consortium of institutes led by MPE (Germany) and including UVIE (Austria); KU Leuven, CSL, IMEC (Belgium); CEA, LAM (France); MPIA (Germany); INAF-IFSI/OAA/OAP/OAT, LENS, SISSA (Italy); IAC (Spain). This development has been supported by the funding agencies BMVIT (Austria), ESA-PRODEX (Belgium), CEA/CNES (France), DLR (Germany), ASI/INAF (Italy), and CICYT/MCYT (Spain). Basic research in IR astronomy at NRL is funded by the US ONR; J.F. also acknowledges support from the NHSC. E.G.-A. is a Research Associate at the Harvard-Smithsonian Center for Astrophysics.
