Abstract

For structure-acoustic system with uncertainties, the interval model, the random model and the hybrid uncertain model have been introduced. In the interval model and the random model, the uncertain parameters are described as either the random variable with well defined probability density function (PDF) or the interval variable without any probability information, whereas in the hybrid uncertain model both interval variable and random variable exist simultaneously. For response analysis of these three uncertain models of structure-acoustic problem involving arbitrary PDFs, a unified polynomial expansion method named as the Interval and Random Arbitrary Polynomial Chaos method (IRAPCM) is proposed. In IRAPCM, the response of the structure-acoustic system is approximated by APC expansion in a unified form. Particularly, only the weight function of polynomial basis is required to be changed to construct the APC expansion for the response of different uncertain models. Through the unified APC expansion, the uncertain properties of the response of three uncertain...
models can be efficiently obtained. As the APC expansion can provide a free choice of the polynomial basis, the optimal polynomial basis for the random variable with arbitrary PDFs can be obtained by using the proposed IRAPCM. The IRAPCM has been employed to solve a mathematical problem and a structure-acoustic problem, and the effectiveness of the unified IRAPCM for response analysis of three uncertain models is demonstrated by fully comparing it with the hybrid first-order perturbation method and several existing polynomial chaos methods.

**Key words:** Interval model; Random model; Hybrid uncertain model; Arbitrary Polynomial Chaos; Gauss integration; Structure-acoustic system.

## 1 Introduction

The response analysis of structural-acoustic system is a key procedure for the control and optimization of the vibration and noise behaviors of engineering products, such as automobiles, steamships, aircrafts, submarines and spacecrafts. Traditional methods for response analysis of structural-acoustic system are deterministic numerical methods by assuming that all input parameters are fixed [1]. However, uncertainties related to material properties, boundary conditions and surrounding environment are unavoidable in the real engineering practices. Without considering these uncertainties, the results obtained by using deterministic numerical methods may be unreliable. Therefore, there is a growing interest for developing numerical methods for the response analysis of structural-acoustic system with uncertainties [2-6].

The most widely used technique for uncertainty quantification is the probabilistic method, in which the uncertain parameter is represented by the random variable with well defined *probability density function*(PDF). During past decades, lots of methods have been proposed for random uncertainty quantification, such as the Monte Carlo method [7-9], the perturbation *probabilistic* method [10-13] and the polynomial chaos method [14,15]. Among these methods, the Monte Carlo method is the simplest and the most versatile method for uncertain problems. However, the Monte Carlo method
suffers from tremendous computational cost for large-scale engineering systems[7].
The perturbation probabilistic method is a very efficient way for random analysis, but
it is only accurate for uncertain problems with small uncertainty level[10]. The
polynomial chaos method is proposed based on orthogonal polynomial theory, which
is free from small perturbation assumption and the efficiency is much higher than
Monte Carlo method[14]. Thus, the polynomial chaos method has been widely used to
solve random engineering problems[16-18].

The probabilistic method is established based on the condition that the precise
probability distribution is obtained. However, at the early stage of design, the PDF of
random variables may not be available due to the limited information. To model the
uncertain problems with limited information, various of non-probabilistic
mathematical frameworks have been developed, such as the interval analysis[19-21],
the fuzzy theory[22, 23], the evidence theory[24-26] and the p-box set[27,28]. All
these non-probabilistic mathematical frameworks have their own merit in application.
The fuzzy theory is an effectively technique to model the subjective probability
derived from the expert opinions. The evidence theory and the p-box set are suitable
to represent imprecise probability. In the interval analysis, only the lower and upper
bounds of an uncertain parameter are required. Thus, the interval analysis is most
suitable to describe the uncertainties whose probability information is completely
missing. As the determination of bounds for an interval may be easier and more
straightforward than the identification of an imprecise probability distribution, the
interval analysis is also a popular mathematical framework to deal with the
uncertainties in engineering problems. Researches on uncertainty quantification of
interval model is rather mature and different methods have been proposed, including
the interval perturbation method[29-31], the interval Chebyshev method[32], the
interval Legendre method[33], the interval factor method[34], the vertex method[35],
the rational expansion method[36,37] and et al. More detailed review of interval
methods can be found from Ref.[38].

Obviously, the interval methods and the random methods aforementioned are
focused on uncertain problem with either random or interval parameters. However,
the random and interval parameters may exist simultaneously in some engineering problems. To represent the hybrid uncertainties, Elishakoff and Colombi developed a hybrid uncertain model, in which some uncertain parameters with well defined PDFs are treated as random variables, whereas the others are described as interval variables[39]. The uncertainty quantification of the hybrid uncertain model is more challenging than the interval uncertainty quantification and the random uncertainty quantification, as the approximation for the response related to different types of uncertainty in the hybrid uncertain model should be properly integrated[40]. Up to now, the studies for uncertainty quantification of the hybrid uncertain model are relatively small. The perturbation technique is a general choice for the hybrid uncertain analysis in the last decades, but it is limited to hybrid uncertain problems with small uncertainty level[41-44]. Recently, the polynomial chaos method has been developed for hybrid uncertain analysis. By integrating the Chebyshev polynomial with the generalized Polynomial Chaos(gPC), Wu et. al. proposed a hybrid method for uncertainty quantification and robust topology optimization [45, 46]. Subsequently, Yin et al. employed the Gegenbauer polynomial of gPC to construct a unified polynomial chaos expansion for structure-acoustic problems with interval and/or random uncertainties[47]. Wang et.al developed a response surface method for structural-acoustic systems with random and interval parameters based on the gPC[48]. To improve the computational efficiency for interval analysis of gPC expansion, Xu et. al developed a hybrid uncertainty analysis method by introducing the dimension wise analysis[49]. Compared with the perturbation technique based method, these gPC based methods have shown better accuracy for hybrid uncertain problem with large uncertainty level.

The random model, the interval model and the hybrid uncertain model listed above can be used to describe the uncertain system with interval and/or random variables in different cases according to the available information. For the uncertainty quantification of these three uncertain models, the polynomial chaos method can be effectively used for the uncertain problem with large uncertainty level and the efficiency is much higher than the Monte Carlo method. Thus, this paper will focus on
the application of polynomial chaos method for uncertainty quantification of these
three uncertain models. From the overall perspective, though the polynomial chaos
method has gained a great achievement for uncertainty analysis, some important
issues still remain unresolved. Firstly, as we mentioned before, the polynomial chaos
methods for hybrid uncertain model are generally developed based on the polynomial
basis of gPC. However, the accuracy and efficiency of these gPC based methods may
be deteriorated for hybrid uncertain problem with the probability distribution out of
Askey scheme, as the optimal polynomial basis of polynomial chaos expansion for
uncertainty analysis with the probability distribution out of Askey scheme cannot be
obtained by using gPC\[50\]. Secondly, there is little research on developing the unified
polynomial expansion method for interval model, random model and hybrid uncertain
model, especially when the random parameter of these uncertain models is following
an arbitrary probability distribution. Recently, the Gegenbauer polynomial has been
developed to construct the unified polynomial expansion for interval model, random
model and hybrid uncertain model\[47\]. By using the unified Gegenbauer expansion,
the response for these three uncertain models can be obtained by using a common
numerical algorithm. However, unified Gegenbauer expansion method is only suitable
for the uncertain problem with the bounded random variable following mono-valley
or mono-peak probability distributions\[47\]. As regarding the engineering application,
the PDF of random variable can be an arbitrary function, sometimes may be very
complex. Therefore, it is desirable to develop new unified polynomial expansion
method that can be used for three uncertain models with interval variable and/or
random variable following arbitrary probability distributions.

The aim of the present study is to develop a new unified polynomial expansion
method for response analysis of structure-acoustic systems with interval and/or
random variables. For structure-acoustic systems with interval and/or random
variables, three uncertain models will be considered, namely the interval model, the
random model and the hybrid uncertain model. In order to construct the unified
polynomial expansion for these three uncertain models, the Arbitrary Polynomial
Chaos(APC) which has been successfully applied to uncertainty analysis with random

variable following arbitrary probability distributions[51-53], will be developed for the uncertainty quantification of interval model and hybrid uncertain model. With this development, the unified **Interval and Random Arbitrary Polynomial Chaos method** (IRAPCM) is proposed to predict the response of three uncertain models of structure-acoustic system. In IRAPCM, the response of three uncertain models is approximated by the APC expansion in a unified form. For different uncertain models, only the weight function of polynomial basis is changed to construct the APC expansion. The coefficients of APC expansion are calculated though the Gauss integration. Once the APC expansion for uncertain models is obtained, the uncertain properties of response can be easily computed. The proposed IRAPCM is applied to a simple mathematical problem and a structure-acoustic problem. The effectiveness of IRAPCM for response analysis of interval model, random model and hybrid uncertain model has been investigated by comparing it with the hybrid first-order perturbation method and several existing polynomial chaos methods.

2 Fundamentals of the arbitrary polynomial chaos expansion

This section will briefly summarize the fundamentals of APC theory. Besides, the Gauss integration will be introduced to compute the coefficient of APC expansion due to its robustness and good efficiency. Furthermore, in order to efficiently calculate the weights and nodes of Gauss integration, the polynomial basis of APC expansion is constructed based on the recursive relations of the monic orthogonal polynomial.

2.1 Arbitrary polynomial chaos expansion for a function

A function \( Y(\xi) \) approximated by the APC expansion can be expressed as follows

\[
Y(\xi) = \sum_{i=0}^{N} y_i \phi_i(\xi) \tag{1}
\]

where \( N \) is the retained order of APC expansion, \( y_i \) represents the expansion
The coefficient to be estimated, $\phi_i(\xi)$ denotes the polynomial basis of order $i$, which satisfied the following orthogonality relation

$$\langle \phi_i(\xi), \phi_j(\xi) \rangle = h_i \delta_{ij} \tag{2}$$

where $h_i = \langle \phi^2_i(\xi) \rangle$, $\delta_{ij}$ denotes the Kronecker delta and $\langle \cdot, \cdot \rangle$ denotes the inner product with respect to the weight function in a specific domain $\Omega$. $\langle \phi_i(\xi), \phi_j(\xi) \rangle$ can be expressed as

$$\langle \phi_i(\xi), \phi_j(\xi) \rangle = \int_\Omega \phi_i(\xi) \phi_j(\xi) w(\xi) d\xi \tag{3}$$

where, $w(\xi)$ is the weight function. $w(\xi)$ in the framework of APC theory can be an arbitrary continuous or discrete function, such as the piecewise function. The free choice of the weight function of polynomial basis is the main advantage of APC expansion.

For multi-dimension uncertain problems, $Y(\xi)$ can be approximated by using the tensor order APC expansion as follows

$$Y(\xi) = \sum_{i_1=0}^{N_1} \cdots \sum_{i_L=0}^{N_L} y_{i_1,...,i_L} \phi_{i_1,...,i_L}(\xi) \tag{4}$$

where, $\xi = [\xi_1, \xi_2, ..., \xi_L]$ is a $L$-dimension vector, $N_i (i=1,2,...,L)$ denotes the retained order of APC expansion related to $\xi_i$, $y_{i_1,...,i_L}$ is the expansion coefficient to be estimated, $\phi_{i_1,...,i_L}$ is the $L$-dimension polynomial basis, which is given by

$$\phi_{i_1,...,i_L}(\xi) = \prod_{j=1}^{L} \phi_{i_j}(\xi_j), \quad j = 1,2,...,L, \quad i_j = 1,2,... \tag{5}$$

In the above equation, $\phi_{i_j}(\xi_j)(j=1,2,...,L)$ denotes the polynomial basis related to $\xi_j$, $i_j$ denotes the order of the polynomial basis $\phi_{i_j}(\xi_j)$.

2.2 Construction of polynomial basis for arbitrary given weight functions

In APC expansion, the polynomial basis for a given weight function can be
numerically obtained based on several numerical theories, such as the Gram-Schmidt orthogonalization[51] and the recursive relations of monic orthogonal polynomials [54]. Gram-Schmidt orthogonalization is the most widely used technique to construct the polynomial basis of APC expansion. However, the polynomial basis obtained by using Gram-Schmidt orthogonalization is not unique for a given weight function. As a comparison, the unique polynomial basis that is orthogonalized to a given weight function can be obtained based on the recursive relations of monic orthogonal polynomials. In addition, the Gauss integration formula for calculating the coefficients of APC expansion can be easily computed according to the coefficients of recursive relations of monic orthogonal polynomials. Therefore, the polynomial basis of APC expansion will be constructed based on the recursive relations of monic orthogonal polynomials in this paper.

Suppose \( w(\xi) \) is a positive measure supported on an interval such that all moments \( \mu^k = \int_{\Omega} \xi^k w(\xi) d\xi \) exist and are finite. Then, there always exist a set of monic orthogonal polynomials that satisfied the following three-term recurrence relations[54]

\[
\begin{align*}
\phi_0(\xi) &= 0, \\
\phi_1(\xi) &= 1, \\
\phi_{k+1}(\xi) &= (\xi - a_k)\phi_k(\xi) - b_k \phi_{k-1}(\xi), \quad k = 0, 1, 2, \ldots
\end{align*}
\]

(6)

Where, \( a_k \) and \( b_k (k=1, 2, \ldots) \) are the recurrence coefficients of the orthogonal polynomials. In the framework of gPC, the recurrence coefficient of the orthogonal polynomial from the Askey scheme is well defined. As a comparison, the recurrence coefficient of the orthogonal polynomials of the APC expansion should be estimated. According to the theory of orthogonal polynomial, \( a_k \) and \( b_k (k=1, 2, \ldots) \) of the APC expansion can be determined by[44]

\[
\begin{align*}
a_k &= \frac{\langle \xi \phi_1(\xi), \phi_k(\xi) \rangle}{\langle \phi_1(\xi), \phi_k(\xi) \rangle}, \quad k = 0, 1, 2, \ldots \quad (7) \\
b_k &= \frac{\langle \phi_{k-1}(\xi), \phi_k(\xi) \rangle}{\langle \phi_{k-1}(\xi), \phi_{k-1}(\xi) \rangle}, \quad k = 1, 2, \ldots
\end{align*}
\]
with the coefficient $b_0$ being arbitrary and set by convention such that
\[ b_0 = \int w(x)dx. \]

2.3 Calculation of the expansion coefficient by using the Gauss integration

Owing the orthogonality of the polynomial basis, the expansion coefficient $y_i$ in Eq. (1) can be obtained via the following expression [54]
\[ y_i = \frac{\langle Y(\xi)\varphi_i(\xi) \rangle}{\langle \varphi_i(\xi),\varphi_i(\xi) \rangle} = \frac{1}{h_i} \int_\Omega Y(\xi)\varphi_i(\xi)w(\xi)d\xi \]  
\[ (9) \]

Lots of integration techniques can be employed to calculate the integral in the above equation, such as the Gauss integration technique [54], the Clenshaw–Curtis integration technique [58] and the Newton–Cotes integration technique [59]. The Gauss integration technique is a widely used integration method for calculating the coefficient of the tensor-order polynomial chaos expansion [16]. This is because the Gauss integration technique can generally achieve high accuracy for determining the integral of the polynomial function, when the number of Gauss nodes is up to a certain value [54]. In this paper, the Gauss integration technique is introduced to calculated the integral in Eq. (9) due to its robustness.

By using Gauss integration rule, $y_i$ in Eq. (9) can be expressed as a weighted sum of a finite set of function evaluations, that is [54]
\[ y_i = \frac{1}{h_i} \int_\Omega Y(\xi)\varphi_i(\xi)w(\xi)d\xi = \frac{1}{h_i} \sum_{i=1}^{m} Y(\tilde{\xi}_i)\varphi_i(\tilde{\xi}_i)w_i \]  
\[ (10) \]

Where, $\tilde{\chi}_i$ and $w_i$ are the nodes and weights of the Gauss integration rule, respectively; $m$ is the total number of integration nodes. $\tilde{\xi}_i$ and $w_i$ of the $m$-point Gauss integration only depend on $w(\xi)$. When $w(\xi)$ is a weight function of the orthogonal polynomial from the Askey scheme, $\tilde{\xi}_i$ and $w_i$ of the $m$-point Gauss integration can be determined by an explicit formula [14]. However, there is no...
explicit formula to determine $\xi_i$ and $w_i$ of the $m$-point Gauss integration for arbitrary weight functions. According to Ref.[54], $\xi_i$ and $w_i$ of the Gauss integration with regard to an arbitrary weight function should be obtained from the eigenvalue decomposition of the Jacobi matrix $J_n$. The Jacobi matrix $J_n$ assembled with the recurrence coefficients $a_i$ and $b_i$ can be expressed as[54]

$$J_n = \begin{bmatrix}
a_0 & \sqrt{b_1} & & \\
\sqrt{b_1} & a_1 & \sqrt{b_2} & \\
& \ddots & \ddots & \ddots \\
& & a_{n-2} & \sqrt{b_{n-1}} & \\
& & & \sqrt{b_{n-1}} & a_{n-1}
\end{bmatrix}$$  \hspace{1cm} (11)

In particular, if $V^TJ_nV = \text{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n)$ and $V^TV = I$, in which $I$ is the $n \times n$ dimension identity matrix. Then, the desired $x_i$ and $\hat{w}_i$ can be determined by

$$x_i = \lambda_i, \quad \hat{w}_i = b_{0,i}v^2_i, \quad i = 1, 2, \ldots$$  \hspace{1cm} (12)

where $v_i$ is the first component of the $i$-th column vector of $V$.

Similarly, the expansion coefficient $y_{i\rightarrow L}$ shown in Eq.(4) can be determined according to the orthogonality of the polynomial basis and expressed as

$$y_{i\rightarrow L} = \frac{\langle Y(\xi), \varphi_{i\rightarrow L}(\xi) \rangle}{\langle \varphi_{i\rightarrow L}(\xi), \varphi_{i\rightarrow L}(\xi) \rangle} = \frac{1}{h_{i\rightarrow L}} \int_{\Omega} Y(\xi) \varphi_{i\rightarrow L}(\xi) w_{i\rightarrow L}(\xi) d\xi$$  \hspace{1cm} (13)

where

$$h_{i\rightarrow L} = \prod_{j=1}^{i} h_j \quad \text{and} \quad w_{i\rightarrow L}(\xi) = \prod_{j=1}^{i} w_j(\xi_j)$$  \hspace{1cm} (14)

By using the Gauss integration, $y_{i\rightarrow L}$ can be obtained and expressed as
\[ y_{n-k} = \frac{1}{h_{n-k}} \int_{\Omega} Y(\xi) \varphi_{n-k}(\xi) w_{n-k}(\xi) d\xi \]

\[ = \frac{1}{h_{n-k}} \sum_{k=1}^{m} \sum_{l=1}^{m} Y(\xi_{k-l}) \varphi_{j}(\xi_{j-l}) W_{j-l} \]

(15)

where

\[ \hat{\xi}_{h-j} = [\xi_{h}, \xi_{h}, ..., \xi_{h}] \]

\[ w_{h} = \prod_{k=1}^{j} w_{h} \]

(16)

In the above equations, \( \hat{\xi}_{h} \) denotes the \( j \) th integration nodes for \( \xi_{h} \), and \( w_{h} \) denotes the weight of Gauss integration related to \( \hat{\xi}_{h} \), \( m_{k} \) \( (k = 1, 2, ..., L) \) denotes the total number of integration nodes related to \( \xi_{h} \).

3 Three uncertain models of structure-acoustic systems with interval and/or random variables

3.1 Dynamic equilibrium equation for structure-acoustic system with uncertain parameters

Without considering the structural damping, the dynamic equilibrium equation of the structure-acoustic system under the time harmonic external excitation derived from finite element analysis can be expressed as

\[ \begin{bmatrix} K - \omega^2 M_s & -H \\ \rho_f \omega^2 H^T & K_f - \omega^2 M_f \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix} = \begin{bmatrix} F_s \\ F_f \end{bmatrix} \]

(17)

where \( \omega \) is the angular frequency of external excitation; \( \rho_f \) is the density of fluid in the acoustic cavity; \( K_s \) and \( M_s \) are the stiffness matrix and the mass matrix of the vibrating structure; \( K_f \) and \( M_f \) are the stiffness matrix and the mass matrix of the acoustic cavity; \( H \) is the spatial coupled matrix; \( F_s \) and \( F_f \) are the generalized force vectors loading on the vibrating structure and the acoustic cavity, respectively;
\[ \mathbf{u}_s \] and \( \mathbf{p} \) are the displacement vector of the vibrating structure and the sound pressure vector in the acoustic cavity, respectively.

For the sake of simplicity, Eq. (17) can be rewritten as

\[ \mathbf{ZU} = \mathbf{F} \]  

(18)

where

\[ \mathbf{Z} = \begin{bmatrix} \mathbf{K}_s - \omega^2 \mathbf{M}_s & -\mathbf{H} \\ \rho \omega \mathbf{H}^t & \mathbf{K}_m - \omega^2 \mathbf{M}_m \end{bmatrix}, \quad \mathbf{U} = \begin{bmatrix} \mathbf{u}_s \\ \mathbf{p} \end{bmatrix}, \quad \mathbf{F} = \begin{bmatrix} \mathbf{F}_s \\ \mathbf{F}_m \end{bmatrix} \]  

(19)

In the above equations, \( \mathbf{Z} \), \( \mathbf{U} \) and \( \mathbf{F} \) denote the dynamic stiffness matrix, the response vector and the force vector of the structure-acoustic system, respectively.

Due to the unpredictable environment and the manufacturing tolerance, the structure-acoustic system always involved uncertainties. By using the vector \( \mathbf{x} = [x_1, x_2, \ldots, x_f] \) to represent the uncertain parameters, the dynamic equilibrium equation of the structure-acoustic system can be rewritten as

\[ \mathbf{Z}(\mathbf{x})\mathbf{U}(\mathbf{x}) = \mathbf{F}(\mathbf{x}) \]  

(20)

Where \( \mathbf{Z}(\mathbf{x}) \) and \( \mathbf{F}(\mathbf{x}) \) denote the uncertain structure-acoustic dynamic stiffness matrix and the uncertain force vector, respectively.

### 3.2 Definition of three uncertain models for uncertain structure-acoustic system

In this paper, the uncertain parameter of structure-acoustic system is treated as either random or interval variable. When there is sufficient data to construct the PDF of \( x_i \), \( x_i \) can be modeled by a random variable \( x_i^R \) and denoted as \( x_i = x_i^R \). When the PDF of \( x_i \) is not available due to the limited information, the variable \( x_i \) can be described by an interval variable \( x_i^I \) and denoted as \( x_i = x_i^I \in [\underline{x}_i, \bar{x}_i] \). According to the available PDF of uncertain parameters, the interval model, the random model and the hybrid uncertain model will be introduced to treat with the uncertain parameters.
Case 1: the interval model

In the interval model, each of the uncertain parameters is described as the interval variable. Accordingly, the uncertain vector \( \mathbf{x} \) can be described as an interval vector and expressed as

\[
\mathbf{x} = \mathbf{x}' = [x'_1, x'_2, ..., x'_L]
\]  

(21)

Case 2: the random model

In the random model, all of the uncertain parameters are described as the random variables and the uncertain vector \( \mathbf{x} \) can be expressed as

\[
\mathbf{x} = \mathbf{x}^R = [x^R_1, x^R_2, ..., x^R_L]
\]

(22)

Case 3: the hybrid uncertain model

In the hybrid uncertain model, the interval variable and the random variable exist simultaneously. In this case, the uncertain vector \( \mathbf{x} \) can be expressed as a hybrid vector, which can be expressed as

\[
\mathbf{x} = [\mathbf{x}', \mathbf{x}^R] = [x'_1, x'_2, ..., x'_L, x^R_1, ..., x^R_L]
\]

(23)

Where, \( L_1 \) denotes the number of interval variables of the hybrid uncertain model. From Eqs.(21)~(23), one can find that the interval model is a special case of the hybrid uncertain model when \( L_1 = L \), while the random model can be viewed as a special case of the hybrid uncertain model when \( L_1 = 0 \).

4 **Arbitrary polynomial chaos expansion for response analysis of structure-acoustic system with interval and random variables**

The APC has been previously applied for random analysis[18]. In this section,
the APC will be developed for response analysis of hybrid uncertain model of structure-acoustic system. As we mentioned in Section 3.2, both the interval model and the random model can be viewed as the special case of the hybrid uncertain model. Therefore, through the extension of APC expansion for hybrid uncertainty analysis, a unified polynomial expansion approach is consequently established for response analysis of the interval model, the random model and the hybrid uncertain model of structure-acoustic system. In the following subsections, the procedure of APC expansion for hybrid uncertainty analysis of structure-acoustic problem will be deduced in detail.

4.1 Determine the polynomial basis with respect to the random variable

Polynomial chaos method is an uncertainty propagation approach which has been used in many engineering problems. The key idea of polynomial chaos method for random analysis is to approximate the random response by a sum of orthogonal polynomials. In the infinite amount of orthogonal polynomials, there always exists an optimal orthogonal polynomial for a given random variable. In particular, the orthogonal polynomial whose weight function is identical to the PDF of random variable can be viewed as the optimal polynomial basis of the polynomial chaos expansion for the random variable[50]. When the optimal polynomial basis is obtained, the polynomial chaos method can achieve exponentially convergence rate for random problem. Thus, in this paper, the PDF is used as the weight function of the polynomial basis with related to the random variable. Once the weight function related to a random variable is determined, the polynomial basis can be calculated through Eqs.(6)–(8).

Note that the widely used gPC can only provide the optimal orthogonal polynomial for the probability distribution in the Askey scheme[14]. As a comparison, the APC can provide the optimal polynomial basis for any probability distribution, which is the main advantage of the APC expansion for uncertainty analysis with random variable.
4.2 Determine the polynomial basis with respect to the interval variable

Theoretically, an arbitrary orthogonal polynomial that is defined on a closed interval can be used as the polynomial basis of APC expansion for the approximation of response of uncertain system with interval variable. However, the accuracy of APC expansion for the interval problem may change with different polynomial bases. Therefore, it is necessary to determine a suitable polynomial basis of APC expansion for interval analysis. According to Section 2.2, the polynomial basis of APC expansion is determined by its corresponding weight function. In order to determine the polynomial basis of APC expansion for the interval problem, the effect of the weight function of polynomial basis on the accuracy of the APC expansion will be firstly investigated and discussed by a simple example as follows.

Example. Consider \( y = f(x) = e^{x^2} \), where \( x \in [-1,1] \). The APC expansions with different weight functions are used to approximate the original function \( f(x) \). The Legendre polynomial and the Chebyshev polynomial are widely used for interval analysis, thus the weight functions of Legendre polynomial and Chebyshev polynomial will be considered to construct the APC expansion in this numerical example. According to ref.[55], the weight functions of both Legendre polynomial and Chebyshev polynomial can be viewed as the special case of the \( \lambda \) function. The \( \lambda \) function is defined as follows[55]

\[
\rho(x,\lambda) = \frac{\Gamma(\lambda+1)}{\Gamma(1/2)\Gamma(\lambda+1/2)}(1-x^2)^{\lambda-1/2}, \quad -1 \leq x \leq 1
\]  

(24)

In particular, the weight function of Legendre polynomial and Chebyshev polynomial are \( \rho(x,0.5) \) and \( \rho(x,\lambda \to 0) \), respectively. In this paper, \( \rho(x,\lambda = 0.01) \) is used instead of \( \rho(x,\lambda \to 0) \). Thus, APC expansions with the weight function \( \rho(x,\lambda = 0.01) \) and \( \rho(x,\lambda = 0.5) \) will be used for the approximation of \( y \). For a comparison the APC expansion with the weight function \( \rho(x,\lambda = 3) \) will also be considered. Three weight functions, namely \( \rho(x,\lambda) \) with
\( \lambda = 0.01, 0.5 \) and 3, are plotted in Fig.1.

Define the Relative error (Re) as

\[
Re = \left| \frac{P(x) - f(x)}{f(x)} \right|
\]

(25)

Where, \( P(x) \) denotes the APC expansion. The relative error of the fifth-order APC expansion with different weight functions is plotted in Fig.2.

It can be found from Fig.2 that the errors yielded by the APC expansions with the weight functions \( \rho(x, \lambda = 0.01) \) and \( \rho(x, \lambda = 0.5) \) are more uniformly distributed over the interval than the APC expansion with the weight function \( \rho(x, \lambda = 3) \). Especially, the accuracy of the APC expansion with the weight function \( \rho(x, \lambda = 3) \) will be seriously deteriorated around the bounds of the interval. The main reason is that the values of \( \rho(x, \lambda = 3) \) at the neighborhood of bounds are very small. Note that the weight function is always used to minimize the residual error of APC expansion[56]. Thus the error of APC expansion may be relatively large on the region where the values of the weight function approach to zeros. Besides, we can find that the errors of APC expansion with the weight function \( \rho(x, \lambda = 0.01) \) around the bounds of interval are relatively smaller than those of APC expansion with the weight function \( \rho(x, \lambda = 0.5) \). This is mainly because the values of \( \rho(x, \lambda = 0.01) \) around the bounds of interval are larger than those of \( \rho(x, \lambda = 0.5) \). Thus, the APC expansion with the weight function \( \rho(x, \lambda = 0.01) \) can achieve relatively high accuracy around the bounds of interval.

The interval analysis is to search the maximum and minimum of a function over the whole closed interval of uncertain input, and the maximum and minimum of a function may be obtained at any value of the closed interval of uncertain input. Thus,
it is ideal to use the approximation technique that can achieve the same accuracy over
the whole interval of uncertain input for interval analysis. However, as is shown in
Fig.2, the accuracy of APC expansion with each weight function will fluctuate in the
interval. Namely, the ideal approximation for interval problems may be not available
by using the APC expansion. But from an overall point of view, the accuracy of the
APC expansions with the weight functions $\rho(x, \lambda = 0.01)$ and $\rho(x, \lambda = 0.5)$ is
more uniformly distributed in the interval than the APC expansion with the weight
functions $\rho(x, \lambda = 3)$. It indicates that it is more suitable to select $\rho(x, \lambda = 0.01)$ or
$\rho(x, \lambda = 0.5)$ rather than $\rho(x, \lambda = 3)$ as the weight function of the polynomial basis
of APC expansion for interval analysis. On the other hand, as regarding engineering
problems, the maximum or minimum of the response is more likely to be obtained at
the bounds of interval. Thus, the APC expansion with the weight function
$\rho(x, \lambda = 0.01)$, which can achieve relatively high accuracy at the bounds of interval,
will be used for interval analysis in this paper. In other words, $\rho(x, \lambda = 0.01)$, namely
the $\lambda$ function with $\lambda = 0.01$, will be adopted as the weight function of the
polynomial basis of APC expansion for interval analysis.

4.3 Construct the arbitrary polynomial chaos expansion for response with interval
and random variables

Based on the APC expansion, the response of the hybrid uncertain
structure-acoustic system can be approximated as

$$U_k = U_k(x^I, x^R) = \sum_{i=0}^{N_j} \sum_{i=0}^{N_j} f_{i_1, \ldots, i_L}^k \phi_{i_1, \ldots, i_L}(x^I) \phi_{i_1, \ldots, i_L}(x^R) \quad k = 1, 2, \ldots, N_{tot} \quad (26)$$

In the above equations, $U_k(k = 1, 2, \ldots, N_{tot})$ denotes $k$-th element of the response
vector $U$; $N_{tot}$ denotes the dimension of $U$; $N_j(j = 1, 2, \ldots, L)$ denotes the retained
order of APC expansion related to $x_j$, $f_{i_1, \ldots, i_L}^k$ denotes the expansion coefficient to
be estimated. The coefficients $f_{k|\cdot h}$ can be calculated according to section 2.3, which can be determined by

$$f_{k|\cdot h} \approx \frac{1}{h_{1} \times \cdots \times h_{L}} \sum_{l_{i} \cdot \cdot \cdot} \sum_{l_{i} \cdot \cdot \cdot} U(k, \hat{x}) \varphi_{l_{i} \cdot \cdot \cdot l_{i}}(\hat{x}) \varphi_{l_{i} \cdot \cdot \cdot l_{i}}(\hat{x}) w_{l_{i} \cdot \cdot \cdot l_{i}}$$  \hspace{1cm} (27)

In the above equation, $\hat{x}$ and $\hat{x}$ denote the integration nodes related to the interval variables and random variables, respectively. $w_{l_{i} \cdot \cdot \cdot l_{i}}$ denotes the weight with respect to the integration nodes. The integration nodes and their corresponding weight can be calculated through Eqs.(11) and (12); $U(k, \hat{x})$ denotes the responses of structure-acoustic system at the integration nodes, which can be calculate through Eq.(18).

4.4 Evaluate the uncertainty property of sound pressure of structure-acoustic system

The response analysis of uncertain structure-acoustic system with interval and random variables includes two main steps. In the first step, the interval variables are regarded as constant parameters, and the response of hybrid uncertain structure-acoustic system can be rewritten as the following form

$$U(k) = \sum_{l_{i} \cdot \cdot \cdot} \sum_{l_{i} \cdot \cdot \cdot} \sum_{l_{i} \cdot \cdot \cdot} \sum_{l_{i} \cdot \cdot \cdot} f_{k|\cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}}$$  \hspace{1cm} (28)

Where

$$z_{l_{i} \cdot \cdot \cdot l_{i}} = \sum_{l_{i} \cdot \cdot \cdot} \sum_{l_{i} \cdot \cdot \cdot} f_{k|\cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}}$$  \hspace{1cm} (29)

Based on the APC expansion, the expectation of $U(k)$ can be determined by

$$\mu_{U(k)} = \mathbf{E} \left[ \sum_{l_{i} \cdot \cdot \cdot} \sum_{l_{i} \cdot \cdot \cdot} z_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \right]$$  \hspace{1cm} (29)

$$= \int_{\triangle} \cdots \int_{\triangle} \left( \sum_{l_{i} \cdot \cdot \cdot} \sum_{l_{i} \cdot \cdot \cdot} z_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \varphi_{l_{i} \cdot \cdot \cdot l_{i}} \right) dx_{l_{i} \cdot \cdot \cdot} dx_{l_{i} \cdot \cdot \cdot}$$
In the above equation, \( P_{x_j}(x_j^e) (j = L_a + 1, ..., L) \) is the PDF of \( x_j^e \), and there is \( P_{x_j}(x_j^e) = w_j(x_j^e) \), where \( w_j(x_j^e) \) is the weight function of the polynomial basis related to \( x_j^e \). As the polynomial basis is orthogonal with respect to the PDF of the random variable, the analytical solution of the expectation of the APC expansion can be readily obtained[14]. According to Ref.[14], the expectation of the response approximated by APC expansion can be expressed as

\[
\mu_{U_k} = z_k^{0 \ldots 0} \tag{31}
\]

Before calculating the variance of the response, the expectation of mean square response should be obtained, which can be written as

\[
E\left[ (U_k)^2 \right] = E \left[ \sum_{l_{i_a}=0}^{N_{i_a}} \sum_{l_{i_b}=0}^{N_{i_b}} z_{l_{i_a} \ldots l_{i_b}} h_{l_{i_a}} \ldots h_{l_{i_b}} \varphi_{l_{i_a} \ldots l_{i_b}}(x^e) \right]^2 \tag{32}
\]

Based on the orthogonal relationship of polynomial basis, the expectation of mean square response can be finally obtained and written as [14]

\[
E\left[ (U_k)^2 \right] = \sum_{l_{i_a}=0}^{N_{i_a}} \sum_{l_{i_b}=0}^{N_{i_b}} \left( z_k^{l_{i_a} \ldots l_{i_b}} \right)^2 h_{l_{i_a}} \ldots h_{l_{i_b}} \tag{33}
\]

Consequently, the variance of the response can be obtained and expressed as

\[
\sigma_{U_k}^2 = E\left[ (U_k)^2 \right] - \mu_{U_k}^2 \tag{34}
\]

\[
= \sum_{l_{i_a}=0}^{N_{i_a}} \sum_{l_{i_b}=0}^{N_{i_b}} \left( z_k^{l_{i_a} \ldots l_{i_b}} \right)^2 h_{l_{i_a}} \ldots h_{l_{i_b}} - \left( z_k^{0 \ldots 0} \right)^2
\]

Owing to the orthogonality of the polynomial basis, the expectation and variance of the response can be determined and expressed as

\[
\mu_{U_k} = E \left[ \sum_{l_{i_a}=0}^{N_{i_a}} \sum_{l_{i_b}=0}^{N_{i_b}} z_{l_{i_a} \ldots l_{i_b}} \varphi_{l_{i_a} \ldots l_{i_b}}(x^e) \right] = z_k^{0 \ldots 0} \tag{35}
\]
\[ \sigma_{z_i}^2 = E \left[ \sum_{l_i=0}^{N_{l_i}} \sum_{\lambda_i=0}^{N_{\lambda_i}} z_{l_i+\lambda_i}^k \varphi_{l_i+\lambda_i} (x^k) \right]^2 \left( \mu_{z_i} \right)^2 \]
\[ = \sum_{l_i=0}^{N_{l_i}} \sum_{\lambda_i=0}^{N_{\lambda_i}} z_{l_i+\lambda_i}^k h_{l_i} \left( z_{l_i+\lambda_i}^k \right)^2 - \left( z_{0+0}^k \right)^2 \]  

Substituting Eq. (29) into Eq. (35) and Eq. (36), the expectation and variance of the response can be rewritten as

\[ \mu_{z_i} = \mu_{z_i} (x^i) = \sum_{l_i=0}^{N_{l_i}} \sum_{\lambda_i=0}^{N_{\lambda_i}} f_{l_i-\lambda_i} x_{l_i} \varphi_{l_i-\lambda_i} (x^i) \]  

\[ \sigma_{z_i}^2 = \sigma_{z_i}^2 (x^i) = \sum_{l_i=0}^{N_{l_i}} \sum_{\lambda_i=0}^{N_{\lambda_i}} \left( f_{l_i-\lambda_i} x_{l_i} \varphi_{l_i-\lambda_i} (x^i) \right)^2 h_{l_i} \left( f_{l_i-\lambda_i} x_{l_i} \varphi_{l_i-\lambda_i} (x^i) \right)^2 \]

In the second step, the lower and upper bounds of the expectation and variance can be calculated by the Monte Carlo simulation and expressed as

\[ \left[ \mu_{z_i}, \sigma_{z_i} \right] = \left[ \min_{x^i \in [a_i, b_i]} \mu_{z_i} (x^i), \max_{x^i \in [a_i, b_i]} \mu_{z_i} (x^i) \right] \]

To obtain the maximum and minimum of the APC expansion shown in Eq. (39), various methods can be employed, such as the conventional optimization method[54], the Monte Carlo method[47], the interval arithmetic[37], and the dimension wise analysis[49]. The Monte Carlo method is the most accurate approach for interval analysis. However, a large number of sampling points is required to achieve a prescribed accuracy by using the Monte Carlo method. The interval arithmetic is the most efficient method for interval analysis, but its accuracy can hardly be evaluated due to the wrapping effect. The dimension wise analysis can also achieve high efficiency for interval analysis. However, the main potential limitation for dimension wise analysis is that the cooperative effects of multiple interval parameters acting together upon the system response are ignored. Thus, the accuracy of dimension wise analysis may be decreased in some cases[49]. The Genetic Algorithm(GA) algorithm
is a widely used method for solving complex optimization problems. Generally, the GA algorithm can achieve a prescribed accuracy for the interval analysis through an iterative process, and the computational efficiency of GA algorithm is much higher than the Monte Carlo method. Due to the good accuracy of GA algorithm, the GA algorithm will be employed to calculate the maximum and minimum of the APC expansion in this paper. Note that the APC expansion is a simple function, thus the computational cost suffering the GA algorithm is acceptable.

4.5 Procedure of arbitrary polynomial chaos expansion for uncertainty analysis with interval and random variables

This paper employs the APC expansion to approximate the response of uncertain structure-acoustic systems with interval and random variables. Based on the APC expansion, the interval and random analysis of uncertain structure-acoustic systems can be easily implemented. For structure-acoustic systems with different type of uncertain variables, only the weight function should be changed to construct the APC expansion. The proposed method, which can provide a unified approximation for the response of structure-acoustic systems with interval and random variables, is termed as the Interval and Random Arbitrary Polynomial Chaos Method (IRAPCM). The procedures of IRAPCM for structure-acoustic systems with interval and random variables can be summarized as follows

*Step 1.* Determine the weight function of polynomial basis with respect to each variable. For the random variable, the weight function is the same as the PDF; for the interval variable, the weight function is given as the $\lambda$ function with $\lambda = 0.01$;

*Step 2.* Construct the polynomial basis that is orthogonalized with respect to the weight function related to each variable through Eqs. (6)–(8);

*Step 3.* Compute the integration nodes and weights through Eq. (12);

*Step 4.* Calculate the response of structure-acoustic system at the interpolation points through Eq. (20);

*Step 5.* Calculate the coefficients of APC expansion through Eq. (27);
Step6. Calculate the response of structure-acoustic systems with interval and random variables through Eq.(39).

The main difference between the proposed IRAPCM and the conventional gPC based method is that different types of orthogonal polynomials are used for the polynomial chaos expansion. In the gPC based method, the orthogonal polynomial is selected from the Askey scheme, while the orthogonal polynomial in the proposed IRAPCM is numerically generated. As the choice of polynomials in Askey scheme is limited to some well known orthogonal polynomials, the optimal polynomial basis of polynomial chaos expansion for a wide range of complex probability distributions is not available by using the gPC based methods[50]. As a comparison, the optimal polynomial basis for an arbitrary PDF can be constructed by using IRAPCM. In other words, the proposed IRAPCM has the ability to provide the optimal polynomial basis for the uncertain problem involving arbitrary probability distribution.

5 Numerical examples

In previous years, lots of polynomial chaos methods have been proposed for uncertainty quantification of interval model, random model and hybrid uncertain model. To verify the good accuracy of the proposed IRAPCM, several widely used polynomial chaos methods have been introduced for comparison. For the response analysis of interval model, the widely used Interval Legendre method(ILM[33]) and the Interval Chebyshev method(ICM[5]) are introduced. For the response analysis of random model, the gPC method(gPCM[14]) is introduced. For the hybrid uncertain analysis, the hybrid gPC and Interval Chebyshev method(gPC-ICM[46]) and the hybrid gPC and dimension wise analysis method(gPC-DWM[49]) are introduced.

5.1 Mathematical problem

Consider a function as follows
\[ y = e^{x^2} + x e^{x^2} \]  (40)
$x_1$ and $x_2$ are assumed as uncertain parameters. Table 1 listed three uncertain models to describe $x_1$ and $x_2$.

In the interval model, both $x_1$ and $x_2$ are described as interval variables. As the PDF of the interval variable is not available, only the range of variation is given for the interval variable. In the random model, both $x_1$ and $x_2$ are described as random variables. In the hybrid uncertain model, $x_1$ is described as random variable, while $x_2$ is described as interval variable. In Table 1, the PDFs of $\xi_1$ and $\xi_2$ are given as follows

$$p_{\xi_1}(\xi) = \begin{cases} a_0 (1-\xi^2)^3 & -1 \leq \xi \leq -0.1 \\ a_0 (1-0.1^2)^3 & -0.1 < \xi < 0.1 \\ a_0 (1-\xi^2)^3 & 0.1 \leq \xi \leq 1 \end{cases} \quad (41)$$

$$p_{\xi_2}(\xi) = \frac{2\Gamma(\lambda + 1)}{\Gamma(1/2)\Gamma(\lambda + 1/2)} \left(4\xi - 3\right)^{\lambda + 1/2} \left(2 - \sqrt{4\xi - 3}\right)^{\lambda - 1}, \quad \xi \in [0.75, 1.75] \quad (42)$$

In the above equations, $a_0$ can be determined by $\int_{-1}^{1} p_{\xi_1}(\xi) \, d\xi = 1$; $\lambda$ is the distribution parameter, which can be any value of $\lambda \geq 0$. In this numerical example, $\lambda$ is taken as 2.5. Both PDFs of $\xi_1$ and $\xi_2$ are out of the Askey scheme. $\xi_1$ cannot be represented by using the random variable with the PDF from the Askey scheme, while $\xi_2$ can be represented by using the second order polynomial function of the random variable with $\lambda$ distribution from the Askey scheme[52], that is

$$\xi_2 = 1 + 0.5 \xi^\lambda + 0.25 \left(\xi^\lambda\right)^2, \quad \xi_\lambda \in [-1, 1] \quad (43)$$

Specially, $\xi^\lambda$ with the $\lambda$ distribution is related to the Gegenbauer polynomial in the Askey scheme, and the PDF of $\xi^\lambda$ is given by

$$p_{\xi^\lambda}(\xi) = \frac{\Gamma(\lambda + 1)}{\Gamma(1/2)\Gamma(\lambda + 1/2)} \left(1-\xi^2\right)^{\lambda + 1/2}, \quad -1 \leq \xi \leq 1 \quad (44)$$

In the proposed method, the Gauss integration method is adopted to calculate the
The accuracy of the Gauss integration method depends on the number of integration nodes. Generally, the error of Gauss integration method can be reduced by increasing the number of integration nodes. However, the increase of the number of integration nodes will lead to the increase of computational burdens. Thus, to guarantee the accuracy of the Gauss integration and reduce the computational cost, it is important to determine the minimal number of required integration nodes. In order to determine the number of required integration nodes of Gauss integration for calculating the expansion coefficient, the effect of the number of integration nodes on the accuracy of the proposed IRAPCM will be firstly investigated. When the retained order of APC expansion of the IRAPCM is \( n = 1, 2 \) and 3, the relative errors of the lower and upper bounds of interval model yielded by IRAPCM with different number of integration nodes are plotted in Fig.3. The reference result of the lower and upper bounds of \( y \) is calculated by using the GA algorithm.

Fig.3 shows that the relative error of IRAPCM at a certain retained order is gradually decreased with the increase of the number of integration nodes. When the number of integration nodes is up to \( n+1 \), the relative error yielded by IRAPCM under a certain retained order almost no longer changed. In other words, the accuracy of IRAPCM at a certain retained order can be hardly improved by increasing the number of integration nodes when the number of integration nodes is up to \( n+1 \). Therefore, to minimize the computational burden without losing the accuracy, the number of integration nodes is set as \( n+1 \) in this paper.

The proposed IRAPCM is employed to calculate the response of three uncertain models of the mathematical problem. In order to compare the accuracy of the proposed method to other polynomial chaos based uncertainty method, the ILM, the ICM, the gPCM, the gPC-ICM and the gPC-DWM will also be introduced for response analysis of different uncertain models. The relative errors yielded by different methods are plotted in Fig.4 for the interval model, in Fig.5 for the random model and in Figs.6~7 for the hybrid uncertain model. The reference result of the expectation and variance of \( y \) related to the random variable is obtained by using the
integration method[54], and the reference result of the lower and upper bounds of $y$
related to the interval variable is calculated by using the GA algorithm[57].

From Fig.4, we can find that the accuracy of IRAPCM is the same as that of the
widely used ICM for interval analysis. The main reason may be that the weight
function of the APC expansion in IRAPCM for interval analysis is approximately the
same as the weight function of the Chebyshev polynomial in ICM. However, it should
be noted that the polynomial basis of APC expansion in IRAPCM is different from
that of the Chebyshev polynomial in ICM. For instance, the APC expansion is
constructed based on the monic polynomial, while the high-order Chebyshev
polynomial is not the monic polynomial[32]. Therefore, the Chebyshev polynomial
cannot be viewed as a special case of the polynomial basis of the APC expansion.

When compared with the ILM, it can be observed from Fig.4 that the error of the
lower bound obtained by using IRAPCM is smaller than that of the ILM, while the
error of the upper bound obtained by using IRAPCM is slightly larger than that of
the ILM at several retained orders. This is mainly because that the upper bound of $y$
is obtained at the bounds of $x$, where the APC expansion can achieve higher accuracy
than the Legendre expansion(Refer to Fig.2 in Section 4.2); while the lower bound of
$y$ is obtained around the mind-point of $x$, where the accuracy of APC expansion may
be lower than that of the Legendre expansion. Therefore, the accuracy of IRAPCM is
higher than that of ILM for calculating the upper bound of $y$, but is slightly lower than
that of ILM for calculating the lower bound of $y$.

From Fig.5, we can find that IRAPCM can converge exponentially. As a
comparison, the convergence rate of gPCM is much slower than that of IRAPCM, and
the accuracy of gPCM remains no longer changed when the retained order is up to 3.
This is mainly because the weight function of polynomial basis of gPCM can not
accurately represent the random variable whose PDF is a piecewise function. In other
words, some errors have been introduced for the PDF of random variable by using
gPCM. Consequently, the results obtained by gPCM cannot converge to the exact
result. In addition, the nonlinear transformation of the random variable may also degrade the convergence rate of the gPCM. Therefore, the accuracy of gPCM is much lower than that of the IRAPCM for random problems when the PDF of random parameters is out of the Askey scheme.

From Figs.6 and 7, we can find that IRAPCM can also converge exponentially for hybrid uncertain analysis, while the gPC-ICM and gPC-WDM converges very slowly, especially when the retained order is up to 3. In other words, the IRAPCM can achieve much higher accuracy than the gPC-ICM and the gPC-WDM for hybrid uncertain analysis. As is addressed before, the accuracy of IRAPCM is the same as that of ICM for interval analysis, but is much higher than that of gPCM for random analysis. It indicates that the deterioration of the accuracy of gPC-ICM may be mainly caused by the use of the gPCM for random analysis. Therefore, it is more desirable to use the APC in the proposed method rather than the gPC for uncertainty quantification involving random variables.

As a conclusion from Figs.4–7, the proposed IRAPCM can achieve the same accuracy as the widely used ICM for interval analysis, whereas the accuracy of IRAPCM is much higher than that of the gPC based methods for random analysis and hybrid uncertain analysis. In other words, the proposed IRAPCM can not only keep the good accuracy of ICM for interval analysis, but can also improve the accuracy of the gPC based method for random analysis and hybrid uncertain analysis.

In addition, we can find from Figs.4–7 that the relative error of the proposed IRAPCM for response analysis of three uncertain models is gradually reduced with the increase of the retained order. It indicates that the proposed IRAPCM can achieve a high accuracy for response analysis of three uncertain models if the retained order of APC expansion is sufficiently large.

5.2 Structure-acoustic problem

5.2.1 Description of four cases of structure-acoustic system with interval and random variables

Fig. 8 shows a shell structure-acoustic system, in which the shell is located at the
top of the acoustic cavity. The flexible shell is made of steel ($E = 2.1 \times 10^5 MPa$, $\nu = 0.3$, $\rho_s = 7850 kg/m^3$). The thickness of the shell is 2mm. The acoustic cavity is filled with air ($\rho_f = 1.225 kg/m^3$ and $c = 340.5 m/s$). All edges of the shell are fixed, while the walls of the acoustic cavity are rigid. The shell is excited by a unit normal harmonic point force at middle point denoted as Node B in Fig.8. The Finite Element (FE) method is used to analyze the response of structure-acoustic system. Particularly, the acoustic cavity and the shell structure are discretized by using the quadrilateral elements and the hexahedral elements, respectively. The total number of elements and nodes of the FE model of acoustic cavity are 1024 and 1337. The total number of elements and nodes of the FE model of shell structure are 128 and 153.

Considering the unpredictability of the environment temperature and the manufacturing errors of materials, the Young’s modulus $E$, the thickness $t$, the density of air $\rho_f$ and the speed of air $c$ are considered as the independent uncertain parameters. To validate the accuracy of the proposed method for uncertain problem in different cases, four cases of uncertain structure-acoustic system is considered. The uncertainty information of four cases is listed in Table2. In case1, all uncertain parameters are described as interval variables. In case2, all uncertain parameters are described as random variables. For convenience, the random variables are assumed as a linear function of the unitary random variable defined on $[-1, 1]$. In case3 and case4, both interval variables and random variables existed simultaneously. The uncertainty level of the uncertain variable of case4 is much smaller than that of cases1~3. In Table2, the unitary random variables $\xi^k$ and $\xi^h$ obey the $\lambda$ distribution[55]. The value of $\hat{\lambda}$ for $\xi^k$ and $\xi^h$ are $\hat{\lambda}_1 = 4.5$ and $\hat{\lambda}_2 = 0.5$, respectively. The PDF of $\xi$, is assumed as follows

$$P_{\xi_i}(\xi) = \begin{cases} 
0.84075 \times (1-\xi^2)^3 & -1 \leq \xi \leq -0.2 \\
0.84075 \times (1-0.1^2)^3 & -0.2 < \xi < 0.2 \\
0.84075 \times (1-\xi^2)^3 & 0.2 \leq \xi \leq 1 
\end{cases}$$

(50)
5.2.2 Compared with the hybrid perturbation method

In the last decade, the perturbation method and the polynomial chaos method have been widely used for uncertainty analysis of structure-acoustic system with interval and random variables[3,5,33,40]. Both the perturbation method and the polynomial chaos method have their own merits and application scope. The perturbation method can achieve high computational efficiency, but it is limited to uncertain problem with small uncertainty level. The polynomial chaos method can be employed to solve uncertain problem with large uncertainty level. However, the computational efficiency of the polynomial chaos method is lower than that of the perturbation method. The comparison between the perturbation method and the polynomial chaos method for structure-acoustic system with pure interval uncertainty has been fully discussed in the previous study[5,33]. In this paper, the proposed IRAPCM will be compared to the perturbation method for uncertainty analysis with both interval and random variables. Particularly, the Hybrid First-order Perturbation Method(HFPM) in Ref.[3] will be introduced for comparison. For uncertainty analysis of structure-acoustic system with interval and random variables, two cases with different uncertainty level will be considered. In case 4, the uncertainty level of the interval and random variables is very small, while the uncertainty level of the interval and random variables of case3 is much larger than that of case4. The first-order IRAPCM and the HFPM is employed to calculate the response of case3 and case4 at f=300Hz. In the first-order IRAPCM, the retained order of APC expansion for each uncertain variable is one. The lower and upper bounds of the expectation and variance of sound pressure distributing on the middle section obtained by the HFPM and the first-order IRAPCM are plotted in Figs.9 and 10. The reference results are obtained by using the Monte Carlo simulation. In Monte Carlo simulation, the sampling points for the random variables are 100000, and 10 uniformly distributed sampling points are used for each interval variable.
From Fig. 9, we can find that the results obtained by the HFPM and the first-order IRAPCM are very close to the reference results. It indicates that both the HFPM and the first-order IRAPCM can achieve high accuracy for hybrid uncertainty analysis of structure-acoustic problem with small uncertainty level.

From Fig. 10, we can find that both the HFPM and the first-order IRAPCM will lead to large errors. Namely, the HFPM and the first-order IRAPCM are not suitable to solve the structure-acoustic problem with large uncertainty level. It can be seen from Figs. 6 and 7 that the accuracy of the IRAPCM for hybrid uncertainty analysis can be improved by increasing the retained order. To reduce the computational error of IRAPCM, the high-order IRAPCM will be employed to calculate the response of case3. In the high-order IRAPCM, the retained orders of the APC expansion of IRAPCM are 3, 2, 1 and 5 for $E$, $t$, $\rho_f$ and $c$, respectively. The results obtained by the high-order IRAPCM are plotted in Fig. 11.

It can be seen from Fig. 11 that the result obtained by high-order IRAPCM is very close to the reference result. It indicates that the proposed IRAPCM can achieve high accuracy for uncertainty analysis with large uncertainty level if the retained order is sufficiently large.

Theoretically, the accuracy of the hybrid perturbation method can also be improved by using high-order expansion. However, the computation of the derivatives of the high-order expansion of perturbation method for engineering problem is rather difficult and extremely cumbersome. Thus, the perturbation method for most of engineering problems is developed by using the low-order expansion, such as the first-order expansion and the second-order expansion. For uncertainty analysis of structure-acoustic problem with large uncertainty level, the accuracy of perturbation method cannot be significantly improved by using the second-order expansion instead of the first-order expansion. Therefore, up to now, the hybrid perturbation method is limited for structure-acoustic problem with small uncertainty level.
The computational time of the HFPM and the first-order IRAPCM is 12.8s and 75.2s, respectively. Namely, the efficiency of the HFPM is much higher than that of the first-order IRAPCM for structure-acoustic problem with interval and random uncertainties. Note that the HFPM can achieve high accuracy for uncertain structure-acoustic problem with small uncertainty level. Therefore, to save the computational cost, it is more reasonable to use the HFPM rather than the IRAPCM for response analysis of structure-acoustic problem with small uncertainty level.

5.2.3 Compared with several widely used polynomial chaos methods

In this subsection, the proposed IRAPCM will be compared to several widely used polynomial chaos methods for response analysis of cases1~3. In particular, ICM and ILM are introduced to calculate the response of case1; the gPCM is introduced to calculate the response of case2; and the gPC-ICM and the gPC-WDM are introduced to calculate the response of case3. The retained orders of the polynomial expansion in the polynomial chaos methods are 3, 2, 1 and 5 for \( E, t, \ \rho \) and \( c \), respectively. The reference results are obtained by using the Monte Carlo simulation. In Monte Carlo simulation, the sampling points for the random variables are 100000, and 10 uniformly distributed sampling points are used for each interval variable. The uncertainty property of the sound pressure distributing on the middle section at \( f=300\text{Hz} \) obtained by the proposed method and other methods are plotted in Fig.12 for case1, Fig. 13 for case2 and Fig.14 for case3.

From Fig.12, we can find that all these three polynomial chaos based interval methods, including the proposed IRAPCM, the ICM and the ILM, can achieve high accuracy for the response analysis of case1, and the accuracy of these three interval methods are almost the same. It verifies that IRAPCM can be successfully used for the interval analysis of structure-acoustic problems. From Figs.13 and 14, we can see that the IRAPCM can achieve much higher accuracy than the other polynomial chaos
based methods for case2 and case3, which further verifies merits of the proposed method in accuracy for uncertainty quantification involving random variables.

Computational efficiency is another important index to evaluate the performance of the numerical methods. For response analysis of three uncertain models of structure-acoustic system, there are three main steps in the proposed IRAPCM. Firstly, the polynomial basis is numerically constructed according to the PDF of random variables. Secondly, the polynomial chaos expansion is established for the approximation of the response of the uncertain structure-acoustic system. In particular, the coefficients of polynomial expansion are obtained through the response reanalysis of the structure-acoustic system. For brevity, the response reanalysis of the structure–acoustic system is denoted as RRSS. Finally, uncertainty property of response can be obtained through the interval and random analysis of polynomial chaos expansion (PCE). To illustrate the computational burdens of the proposed method in detail, the total computational time and the computational time of three main steps of the proposed method for three cases are listed in Table3. As a comparison, the computational time of ILM and ICM for Case1, the computational time of gPCM for Case2 and the computational time of gPC-ICM and the gPC-WDM for Case3 are also listed in Table3. All of the computational results are obtained by using MATLAB R2014a on a 3.20GHz Intel(R) Core (TM) CPU i5-3470.

From Table3, we can find that the computational time of the RRSS of each polynomial chaos method is close to its total computational time. It indicates that the computational costs of the polynomial chaos methods for three cases mainly suffer from the RRSS. Besides, we can find from Table3 that the computational time of the RRSS by using different polynomial chaos methods are almost the same. This is mainly because the same retained order is used in these polynomial chaos methods. According to Eqs.(24) and (25), the total number of RRSS is determined by the retained order of polynomial chaos expansion. Therefore, computational time of RRSS by using different polynomial chaos methods will be very close when the same retained order is used in polynomial chaos expansion.
Furthermore, we can find that the execution time of the proposed IRAPCEM is relatively longer than that of the other polynomial chaos based methods under the same retained order. There are two main reasons for the increase of computational cost by using the proposed IRAPCM. First, the interval analysis of PCE in the proposed method is processed by using the GA algorithm. Generally, the computational efficiency of the GA algorithm is lower than the dimension wise analysis (in gPC-WDM and ILM). Second, the orthogonal polynomials in IRAPCM are constructed numerically, while the analytical expression of orthogonal polynomials of the other polynomial chaos methods has been well defined. Thus, in IRAPCM, additional computational time will encountered by constructing the orthogonal polynomial for random variable and interval variable. However, compared with the computational burden suffering from the response reanalysis of structure-acoustic system, the additional computational burdens for both the uncertainty analysis of PCE by using GA algorithm and the computation of polynomial basis are much less.

6 Conclusion

Through an extension of the APC expansion for interval analysis and hybrid uncertain analysis, a unified polynomial chaos method named as IRAPCM, is proposed for response analysis of the interval model, random model and hybrid uncertain model of structure-acoustic system. In IRAPCM, the response of three uncertain models is approximated by the APC expansion in a unified form. Based on the unified APC expansion, the uncertainty property of the response of structure-acoustic system can be efficiently obtained. In the procedure to construct the APC expansion for different uncertain models, only the weight function of polynomial basis is required to be changed. In particular, the \( \lambda \) function with a small value of \( \lambda \) is used as the weight function of polynomial basis for the interval variable, while the weight function of polynomial basis for the random variable is the same as the PDF. For a given weight function, the polynomial basis of APC expansion
is determined based on the recursive relations of monic orthogonal polynomials. As the weight function of polynomial basis of the APC expansion can be an arbitrary continuous or discrete function, the unified APC expansion can be effectively used for response analysis of three uncertain models of structure-acoustic system involving the random variable with arbitrary PDFs.

The proposed IRAPCM has been employed to calculate the response of three uncertain models of a mathematical problems and a structure-acoustic problem. Different uncertainty properties have been obtained for three uncertain models, including the bounds of the response of interval model, the expectation and variance of the response of random model, and the bounds of the expectation and variance of the response of hybrid interval and random model. The merits of the proposed method is demonstrated by comparing it with the hybrid first-order perturbation method and several widely used polynomial chaos methods, including the interval Chebyshev method(ICM), the interval Legendre method(ILM), the generalized Polynomial Chaos method(gPCM), the hybrid generalized Polynomial Chaos and Interval Chebyshev method(gPC-ICM) and the hybrid generalized Polynomial Chaos and dimension wise analysis method(gPC-WDM). Numerical results have shown that: (1) the proposed IRAPCM can achieve high accuracy for interval and random analysis with large uncertainty level if the retained order is sufficiently large; (2) the accuracy of the proposed IRAPCM is the same as that of the widely used ICM for interval analysis; (3) the proposed IRAPCM can achieve higher accuracy than the gPC based methods for random analysis and hybrid uncertain analysis; (4) the computational efficiency of IRAPCM is lower than that of the hybrid first-order perturbation method, but the hybrid first-order perturbation method is limited for structure-acoustic problem with small uncertainty level.

As a conclusion, the proposed method can not only provide a unified polynomial expansion for the response analysis of three uncertain models of structure-acoustic system with interval and/or random variable, but also can achieve better accuracy than the gPC based method for response analysis of random model and hybrid uncertain model of structure-acoustic problems with large uncertainty level. Note that the
computational cost of the proposed IRAPCM is relatively larger than that of the gPC based methods under the same retained order. However, compared with the improvement in accuracy, the increase of computational effort by using the proposed IRAPCM is deemed acceptable.
