Investigating the Subcortical Route to the Amygdala Across Species and in Disordered Fear Responses

ABSTRACT: Over the past few decades, evidence has come to light that there is a rapid subcortical shortcut that transmits visual information to the amygdala, effectively bypassing the visual cortex. This pathway purportedly runs from the superior colliculus to the amygdala via the pulvinar, and thus presents a methodological challenge to study noninvasively in the human brain. Here, we present our recent work where we reliably reconstructed the white matter structure and directional flow of neural signal along this pathway in over 600 healthy young adults. Critically, we found structure-function relationships for the pulvinar-amygdala connection, where people with greater fibre density had stronger functional neural coupling and were also better at recognising fearful facial expressions. These results tie together recent anatomical evidence from other visual primates with very recent optogenetic research on rodents demonstrating a functional role of this pathway in producing fear responses. Here, we discuss how this pathway might operate alongside other thalamo-cortical circuits (such as pulvinar to middle temporal area) and how its structure and function may change according to the sensory input it receives. This newly established circuit might play a potentially important role in autism and/or anxiety disorders.

KEYWORDS: Amygdala, pulvinar, superior colliculus, fear, connectivity

ABSTRACT: Over the past few decades, evidence has come to light that there is a rapid subcortical shortcut that transmits visual information to the amygdala, effectively bypassing the visual cortex. This pathway purportedly runs from the superior colliculus to the amygdala via the pulvinar, and thus presents a methodological challenge to study noninvasively in the human brain. Here, we present our recent work where we reliably reconstructed the white matter structure and directional flow of neural signal along this pathway in over 600 healthy young adults. Critically, we found structure-function relationships for the pulvinar-amygdala connection, where people with greater fibre density had stronger functional neural coupling and were also better at recognising fearful facial expressions. These results tie together recent anatomical evidence from other visual primates with very recent optogenetic research on rodents demonstrating a functional role of this pathway in producing fear responses. Here, we discuss how this pathway might operate alongside other thalamo-cortical circuits (such as pulvinar to middle temporal area) and how its structure and function may change according to the sensory input it receives. This newly established circuit might play a potentially important role in autism and/or anxiety disorders.

It is crucial to our survival that we can rapidly predict, detect, and respond to potential threats in our environment. As highly visual creatures, we have developed sophisticated neural network for processing visual information about the world around us. Both the visual system and the amygdala are arguably the most thoroughly studied components of the brain and yet there is considerable controversy over how these two systems interact to rapidly respond to signs of threat. Specifically, there has been extensive debate over whether the amygdala receives visual input from a short, fast, subcortical pathway from the superior colliculus to the pulvinar.1 It might seem strange that the existence of this so-called ‘subcortical route to the amygdala’ could be so elusive, so much that it divides the neuroscientific community. In fact, the human subcortex is extremely difficult to study due to the problems associated with measuring very deep but also very fast neural activity, posing problems to both fMRI and M/EEG methods. Because of this (and the complete absence of postmortem human studies on this pathway), evidence for the subcortical route to the amygdala has had to be pieced together from an array of different studies using different approaches, each prone to its own set of methodological and interpretative limitations. Thus, there has been a great deal of discussion from opposing viewpoints (see review by Tamietto and de Gelder2 but also the review by Pessoa and Adolphs3).

In recent years, there have been significant advances in human neuroimaging methods that have brought us closer to resolving whether this pathway exists and, if so, what it might be used for. First, the computational methods applied to diffusion magnetic resonance imaging (MRI) images have significantly advanced in how accurately they can reconstruct the underlying white matter structure.4 Second, there now exist multiple consortia around the world that collect high-quality human neuroimaging data from thousands of people, obtaining structural images as well as functional measures from an array of cognitive tasks.4 In our study,5 we exploited these two recent advancements and combined them with a long-standing network modelling method (i.e. dynamic causal modelling)6 to robustly investigate the evidence for a subcortical route to the amygdala in the human brain.

The results from our study provided strong evidence for the presence of an afferent subcortical pathway to the amygdala. Using data from the Human Connectome Project, we successfully reconstructed this pathway in over 600 young healthy adults using sophisticated local and global tractography methods. We also observed strong evidence that neural activity (as indicated by BOLD signal) flowed in a forward direction along this pathway (i.e. from the superior colliculus to the amygdala via the pulvinar; see Figure 1) while participants viewed angry and fearful faces. Taken together, these two findings provide convergent evidence for the presence of an afferent subcortical route to the amygdala in the human brain recruited for face processing.

We then investigated whether people with greater fibre density along this pathway might also have stronger forward-flowing neural connectivity during face viewing or perhaps be better at recognising different facial expressions. We discovered that fibre density along only the second half of the subcortical route significantly covaried with effective connectivity (i.e. people with greater fibre density also had stronger pulvinar-amygdala
The frequency range of warning calls from other rodents. While this rapid subcortical auditory pathway is also present in the human brain, research has focused almost exclusively on auditory signals, particularly those in the amygdala via the medial geniculate nucleus in the rodent brain for transmitting auditory signals, especially threatening stimuli. The amygdala to also be conserved across species. Indeed, a subcortical pathway to the amygdala that transmits threat signals (for mice, this is looming stimuli) and directly triggers fearful behavior. Pathways have been identified from the mouse superior colliculus (which is architecturally similar but functionally dissimilar to the primate brain), to the lateral posterior nucleus of the thalamus (considered analogous to the human pulvinar or the parabigeminal nucleus and on towards the amygdala). These studies provide compelling evidence for a subcortical visual path to the amygdala, even in a species whose primary sensory modality is touch via its whiskers. It is, however, essential to consider the dramatic evolutionary reorganization seen in the primate brain to accommodate vision, as this may render the subcortical route absent or perhaps even redundant (our results, of course, suggest the opposite).

Blindsight describes the remarkable ability of people with a destroyed primary visual cortex (V1) to respond to visual stimuli that they cannot consciously perceive. When presented with a fearful stimulus, these cortically blind patients show significantly greater signal in the superior colliculus, pulvinar, and amygdala than healthy controls. This suggests that visual information, particularly fearful faces, is re-routed away from the damaged visual cortex and transmitted along the alternative, shorter subcortical pathway through the superior colliculus and pulvinar instead. One case study on a cortically blind patient has even shown that there is greater fibre density (as

Dramatic neuroplastic reorganization in the early developmental years of the primate brain. Tectopulvinar pathways actually develop earlier than geniculostriate pathways but are pruned as we get older, leaving the geniculostriate pathways as the dominant transmission of visual information. Hence, the structure or functional relevance of the subcortical route to the amygdala is highly likely to be susceptible to change. Nonetheless, there is evidence that this pathway is intact in adult primates. Most recently, one study successfully traced axonal projections in the macaque brain. They discovered axons connecting the superior colliculus to the pulvinar, the terminals of which overlapped with axons connecting the pulvinar to the amygdala. Previous work has also identified these axonal projections in the tree shrew. Unlike the optogenetic innervation seen in the aforementioned rodent research, these neuroanatomical investigations into the primate brain do not correlate the presence of the subcortical route to a particular functional role. This is where studies on humans have made the biggest impact, originating with the discovery of affective blindsight.

The Malleable Functional Role of the Pulvinar-Amygdala Connection

Blindsight describes the remarkable ability of people with a destroyed primary visual cortex (V1) to respond to visual stimuli that they cannot consciously perceive. When presented with affective stimuli, these cortically blind patients show significantly greater signal in the superior colliculus, pulvinar, and amygdala than healthy controls. This suggests that visual information, particularly fearful faces, is re-routed away from the damaged visual cortex and transmitted along the alternative, shorter subcortical pathway through the superior colliculus and pulvinar instead. One case study on a cortically blind patient has even shown that there is greater fibre density (as...
measured by fractional anisotropy) along the subcortical route in the damaged hemisphere than the intact hemisphere or the brains of healthy controls. This suggests that neural plasticity may have altered the strength of the subcortical route as a result of the patient’s reliance on unconscious visual processing.

An extraordinary case of a 7-year-old boy demonstrates the functional power of neuroplasticity for vision. At 2 weeks old, the boy sustained severe damage to both occipital lobes due to a disorder of fatty acid oxidation. Despite this, as well as significant damage to the eyes themselves (his left eye was completely blind), he reports near-normal conscious vision and can play video games, watch movies, and play soccer. He also performs perfectly on orientation, shape, colour, and face discrimination tasks. Instead of finding changes to the affective subcortical route to the amygdala, diffusion tractography instead revealed a significant increase in structural connections from the lateral geniculate nucleus and pulvinar to V5/MT. This thalamo-cortical circuit has been implicated in blindsight before, as well as in the healthy brain. It presents as a strong contender to the colliculo-pulvinar path to the amygdala we investigated in our study (see Figure 1). Crucially, we observed anatomical evidence for the full colliculo-pulvinar pathway but only found the latter half from the pulvinar to the amygdala to be functionally relevant. This supports the notion that perhaps there is significant cortical input to the pulvinar’s transmission to the amygdala, making it not quite so ‘subcortical’ after all.

Future research is needed to directly compare the contributions of each circuit to producing fear responses in the amygdala. Importantly, this illustrates that visual affective processing is anything but serial. There are many different types of subcortical, cortical, and subcortical-cortical networks all operating in parallel; the specific combination might depend on particular tasks or perhaps is modulated by clinical disorders.

Regardless of whether the pulvinar receives input subcortically or cortically before communicating with the amygdala, the pulvinar-amygdala connection may play an important role in rapid relevance detection. We have previously shown this connection to innervate amygdala activity very quickly (~70 ms poststimulus onset). Other research has demonstrated the role of the pulvinar in relaying visual and higher-order cortical signals to orient attention, facilitate visual search, and recognize emotions. Hence, the pulvinar may gate or amplify information flow to the amygdala and cortex according to an assessment of relevance. Interestingly, people with high trait anxiety show heightened pulvinar-amygdala connectivity, while people with autism show reduced pulvinar-cortical connectivity, suggesting that modulation of this connection may play an important role in psychopathology.

Both autism and anxiety, which can be comorbid, can be characterised by atypical fear responses. People with autism tend to have impaired fear conditioning, atypical amygdala responses to stimuli like fearful faces, as well as unusual fears where, for example, a child with autism may be afraid of umbrellas but not afraid of deep bodies of water. Studies on autism have found that there is weaker structural connectivity along the subcortical route in humans and in an animal model of autism, coinciding with a reduction in typical fear responses. In another study, however, people with autism showed greater BOLD signal in the superior colliculus, pulvinar, and amygdala when fixating on the eyes of fearful faces. Taken together, these findings suggest that the subcortical route may be underused, due to reduced structural connectivity, but then also overused for processing certain visual input like fearful faces. Further research is needed to establish precisely how the subcortical route to the amygdala might be modulated in people higher on the autistic spectrum. Indeed, individual differences in anxiety may play a role in these autism-related findings and may be an interesting avenue to explore. There is already neuropharmacological research using dynamic causal modelling finding that the subcortical route to the amygdala significantly contributes to abnormal fear responses in phobia disorder. Therefore, this points towards a promising avenue of new research into how rapid affective processing subserved by the subcortical route to the amygdala might contribute to disordered fear responses.
