In this paper computer simulation results of higher order density correlation for cellular automaton models of traffic flow are presented. The examinations show the jamming transition as a function of both the density and the magnitude of the noise and allow to calculate the velocity of upstream moving jams. This velocity is independent of the density and decreases with growing noise. The point of maximum flow in the fundamental diagram determines its value. For that it is not necessary to define explicitly jams in the language of the selected model, but only based upon the well defined characteristic density profiles along the line.

I. INTRODUCTION

Recently, the examination and modeling of vehicular traffic has become an important subject of research – see [1]-[3] and references therein for a brief review. In the microscopic approach to the traffic flow problem, the cellular automaton introduced in [6] reproduces important entities of real traffic, like the flow-density relation or stop-and-go waves. Beside the realization of some basic requirements to such a model it can be efficiently used in computational investigations and applications [7]-[10]. Fundamental analytical and numerical examinations enclose exact solutions for certain limits and mean-field approximations [11], the jamming transition [12]-[17] or the effects of perturbations and the occurrence of meta-stable states [18]-[20], e.g. We investigate the density waves and the separation in free-flow and dense regions by means of the density-autocorrelation function. It enables us to trace back the spatio-temporal evolution of jams which are stable during the measurement time, on condition that jams emerge. It should be noted that the probability for a jam to survive decreases with the simulation time [21] in a system without a temporal evolution of jams which are stable during the measurement time, on condition that jams emerge. Therefore this method can be theoretically used for every traffic flow model where density profiles are available. As an example we apply this method to cellular automaton models. In this context we will report and discuss several aspects of the underlying model and their slow-to-start modifications (Section II). The jamming transition shows up by varying both the global density ρ and the global noise p; the jam velocity can be derived directly from the density-autocorrelation function and is closely related to the global flow-density relation (Section II). It is not the goal of the paper to discuss the jamming transition with regard to the criticality or the sharpness of this issue, but we apply the method of correlation function from a more practical point of view.

II. THE MODEL

Within the framework of this paper we only consider a one-dimensional ring of cells. The cells are either vacant or occupied by a vehicle labeled i. Its position is x_i and its discrete velocity is v_i ∈ [0, v_{max}]. The gap g_i denotes the number of empty sites to its leading vehicle. The rules for a parallel update are

- Acceleration with regard to the vehicle ahead: v'_i ← \min(v_i + 1, g_i, v_{max}),
- Noise: with a probability p do v''_i ← \max(v'_i - 1, 0),
- Movement: x_i ← x_i + v''_i.

The investigated systems consist of L cells and N vehicles, the global density is ρ = N/L. The flow is defined as J = ⟨v⟩ρ with the mean velocity ⟨v⟩ = \sum v_i/N. In the following the Nagel-Schreckenberg cellular automaton model [6] defined through the above set of rules is denoted by SCA.

We extend our studies on further modifications of the SCA, namely on models with slow-to-start rules. For the model with velocity-depending randomization (VDR) [19,20] we set \bar{p}(v_i = 0) = \Min(\rho + \varphi_{VDR}, 1). That leads to a reduced outflow from a jam. Note that v_i is the velocity before the first update step is performed. The other modified model under consideration is the T²-model introduced by Takayasu and Takayasu [22]. Here the headway g_i of a
vehicle \(i\) controls the acceleration: standing vehicles with a headway \(g_i = 1\) only speed up with a probability \(1 - \bar{p}\)
with \(\bar{p} = \min(p + p_{T2}, 1)\), whereas for all other ones the rules are unchanged. Unlike the SCA with similar parameters,
both models exhibit a different behavior in the vicinity of the point of maximum flow \((\rho_{\text{max}} \equiv \rho(J_{\text{max}}), J_{\text{max}})\).
They are capable to generate metastable states in the adiabatic approach (for details see [20]), i.e. one finds two branches
of \(J(\rho)\) in a small density interval. Additionally, for sufficient small \(p\) one can find a clear separation of dense
and free-flow regions in a space-time plot. We summarize the effective deceleration probabilities of the applied models:

\[
\begin{align*}
\text{SCA:} & \quad p = \text{const.} \\
\text{VDR:} & \quad \bar{p} = \begin{cases} 
\min(p + p_{VDR}, 1) & \text{if } v_i = 0 \\
p & \text{otherwise}
\end{cases} \\
\text{\(T^2\):} & \quad \bar{p} = \begin{cases} 
\min(p + p_{T2}, 1) & \text{if } v_i = 0 \land g_i = 1 \\
p & \text{otherwise}
\end{cases}
\end{align*}
\]

(1)

Actually, other definitions of \(\bar{p}\) are conceivable, but, for our purpose, we decided to use only the above notations.
Primarily, it was done for modeling moving vehicles with similar properties and to scan the parameter space by varying only \(p\).
Both \(p_{VDR}\) and \(p_{T2}\) are of any value but fix.

### III. Simulation Results and Their Discussion

The density waves are moving upstream and can be easily observed in a space-time plot [6,23], one finds separation of dense and free-flow regions.
For the measurements it is necessary to introduce the mean local density \(\rho_l(k,t)\) of the cell \(k\) at time \(t\):

\[
\rho_l(k,t) = \frac{1}{\lambda} \sum_{i=0}^{\lambda-1} \eta_{k+i}(t)
\]

(2)

with

\[
\eta_{k+i}(t) = \begin{cases} 
1 & \text{if site } k + i \text{ is occupied at time } t \\
0 & \text{otherwise}
\end{cases}
\]

The parameter \(\lambda\) denotes the length of the interval on which the local density has to be computed. It should satisfy the condition \(\lambda_0 \ll \lambda \ll L\) with a characteristic length scale \(\lambda_0\).
For the determination of the jam velocity \(V_J\) we use the generalized \(T\)-point-autocorrelation function of the density

\[
C_{V_J}(r \equiv V_J^* \tau \Delta T, \tau) = \langle \prod_{\tau=0}^{T-1} \rho(x + V_J^* \tau \Delta T, t + \tau \Delta T) \rangle_L
\]

(3)

with the supposed jam velocity \(V_J^* \in [-1,0]\). By varying \(V_J^*\) one finds a largest \(C_{V_J^*}(r, \tau)\) (Fig. 1). \(\Delta T\) is the time interval between two single measurements which contributes to (3).
Sufficiently large values of \(\Delta T\) are necessary to observe a macroscopic motion and to determine \(V_J\) with an adequate accuracy. Unless otherwise mentioned, we set \(L = 10^4\) and \(\Delta T = 10^2\) in order to exclude any finite size effects. Usually, we are averaging over 20 simulation runs with \(v_{\text{max}} = 5\) and \(\lambda = 30\).

As pointed out in Fig. 1 one has to adjust thoroughly the parameters \(T\) and \(\Delta T\). If \(T\) is of the order of magnitude of \(\Delta T\) then the uncertainty of the measurement covers the interesting signal and \(C_{V_J}\) vanishes. This problem becomes more serious while approaching \(\rho^*\). In this region the calculations are complicated additionally due to large fluctuations of \(C_{V_J}\) itself.

The jam velocity \(V_J\) depends on the deceleration probability \(p\) (Fig. 2) and is related to global quantities as it will be shown later. We checked this for a variety of parameters, but could not notice any remarkable deviations among the diverse sets of data. The modifications of the SCA, VDR and \(T^2\), yield a different behavior. The absolute values of the jam velocity in the models VDR and \(T^2\) are smaller than that of the SCA implying that both modifications are characterized by a lowered outflow from a jam that, in turn, reduces the jam velocity.

The results of simulations using the VDR are basically shifted towards smaller \(|V_J|\)'s. \(p_{VDR}\) can be recognized on the ordinate at \(p = 0\) and on the abscissa at \(V_J = 0\), for large \(p\)'s a total deadlock occurs, i.e. it is highly unlikely or even impossible that a stopped car speeds up again. In order to find out how \(V_J\) is related to \(\bar{p}\) we investigate the mean waiting time \(t_w\) for \(\bar{p} < 1\) expressed through an infinite series:
FIG. 1. The peak of the density-autocorrelation function enables to estimate the jam velocity $V_J$. The standard deviation of the symmetrically assumed $C_{V_J}$ is depicted in the inset. For large ratios $T/\Delta T$ the variance shrinks a lot, therefore it might happen that the autocorrelation function vanishes and inhibits the estimation of depending quantities. In the vicinity of $\rho^*$ this sensitivity is more pronounced ($\rho = 0.4$).

FIG. 2. The jam velocity as a function of $p$, the error bars are within the symbol size ($\rho = 0.4$).
Beyond $\rho^*$, especially for $0.2 \leq \rho \leq 0.4$, $V_J(\rho)$ can be assumed to be constant. The inset reveals the large fluctuations of $V_J$ nearby $\rho^*$ which are up to the order of magnitude of $V_J$ itself.

$$t_w = 1(1 - \tilde{p}) + 2(1 - \tilde{p})\tilde{p} + 3(1 - \tilde{p})\tilde{p}^2 \cdots = (1 - \tilde{p}) \sum_{n=1}^{\infty} n\tilde{p}^{n-1} = \frac{1}{1 - \tilde{p}}\]$$

$$\Rightarrow \quad |V_J| = \frac{1}{t_w} = 1 - \tilde{p} \in [0, 1-p_{V,DR}] \tag{4}$$

and is exact for $p = 0$. For large values of $p_{V,DR}$ one obtains a good agreement, whereas for small $p_{V,DR}$ the jam velocity is overestimated. This is due to the so-called sub-jams which emerge downstream a wider jams and cause a reduction of $|V_J|$. The results drawn from simulations using the T$^2$ model show no deadlock situation for any $p < 1$. Starting with $p = 1$, one can hardly distinguish between the simulation results of SCA and T$^2$. Especially, this is valid as long as $p_{T^2} > 1 - p$. Similar to (4) one can estimate

$$t_w = 1(1 - \tilde{p}) + 2(1 - p)\tilde{p} + 3(1 - p)\tilde{p}^2 + 4(1 - p)\tilde{p}^2 \cdots$$

$$= 1 + \tilde{p} \sum_{n=0}^{\infty} p^n = \frac{1 - p + \tilde{p}}{1 - p}. \tag{5}$$

Note that for small $p_{T^2}$-values $V_J$ is overestimated for all values of $p$, which, in turn, can be traced back to the occurrence of sub-jams. With increasing $p_{T^2}$ even for small $p$ it is required to set $\tilde{p} = 1$. Again, it is $|V_J| = t_w^{-1}$ and two special cases can be described by

$$|V_J|(p = 0) = \frac{1}{1 + p_{T^2}} \quad \text{and} \quad |V_J|(p_{T^2} \to 1) = \frac{1 - p}{2 - p}. \tag{6}$$

Obviously, the measurements reveals several density regimes. Below $\rho^*$ the vehicles move independently, i.e. there are no correlations between them. For $\rho \geq \rho^*$ the jam velocity reveals large fluctuations (Fig. 3), which are due to the recurrent emergence and dissipation of jams. But beyond $\rho^*$ $V_J$ is nearly constant. Within the interval where density waves are to be expected it is obvious that $V_J$ is independent of $\rho$, since the outflow from a jam is independent from the global density.

So far, we applied the autocorrelation function (3) to determine the jam velocity. But this quantity itself indicates the two different phases separated by noise $p^*$ or density $\rho^*$ (Fig. 4 and 5). Varying $p$ leads to a transition while crossing $p^*$. Its clarity strongly depends on $T/\Delta T$, for insufficient ratios a plateau at $\bar{C}_{V_J}(p)$ occurs. To elucidate it we used a modified autocorrelation

$$\bar{C}_{V_J}(r, \tau) = \langle (\prod_{\tau=0}^{T-1} \rho_l(x + V_J^* \tau \Delta T, t + \tau \Delta T))^{1/T} \rangle_L. \tag{7}$$

The other transition takes place while crossing the density $\rho^*$ (Fig. 5). For $\rho < \rho^*$ one finds empty regions on the
FIG. 4. The transition from free flow to congested flow can also be obtained in the behavior of the modified autocorrelation function $C_{VJ}$ by varying $p$ ($\rho = 0.073$). The transition is smeared out due to finite size effects and systematic errors in the determination of $C_{VJ}$.

FIG. 5. Plot of the the autocorrelation function $C_{VJ}(\rho)|_{v_{max}}$. Below a signified density the autocorrelation function vanishes due to the absence of jams. The inset zooms into the region $\rho \approx \rho^*$ for the modified autocorrelation $\bar{C}_{VJ}$ ($p = 0.5$).
road of the order of magnitude of $\lambda$, and therefore $C_{VJ}$ completely vanishes. On the other hand, for $\rho > \rho^*$ stable congestion emerge. The same jam can be detected at $t_i$ as well as at $t_f = t_i + \tau \Delta T$ located at $x(t_i) - |V_J|t_f$. In this context, $\rho^*$ can be denoted as the density, at which stable jams emerge and separates the density regime as it is to be seen in the inset of Fig. 5. For a fixed density and a varying $v_{\text{max}}$ (Fig. 6) the relationship can be estimated as $C_{VJ}(v_{\text{max}}) \propto \rho$. Nevertheless, the quality of these data does not allow a correct classification of the transition between the free-flow and the dense region. Above all, the sensitive dependencies on the many adjustable parameters of this method seem to prevent a more accurate consideration of the interesting interval of density.

How is the jam velocity related to other macroscopic quantities? In the steady state the dynamics are characterized by an equilibrium of out-flowing vehicles and vehicles attaching the jam from behind. The more frequent vehicles join the jam the faster the jam moves upstream. If we neglect any effects due to meta-stability then the free-flow region can be assumed to be located in the vicinity of the point of maximum flow ($\rho_{\text{max}}$, $J_{\text{max}}$). Hence, the velocity of attaching vehicles is $\langle v_{\text{att}} \rangle = J_{\text{max}} / \rho_{\text{max}}$. The mean distance between the upstream tail of the jam and the next vehicle is $\langle g \rangle = \rho_{\text{max}}^{-1} - 1$ and the temporal distance therefore reads

$$\Delta t_{\text{att}} = \frac{\langle g \rangle}{\langle v_{\text{att}} \rangle} \iff V_J = \frac{J_{\text{max}}}{\rho_{\text{max}} - 1} \leq 0.$$  

(8)

This is confirmed by the simulation results depicted in Fig. 6. It means that $V_J$ is determined by the slope of the congested branch ($\rho \geq \rho_{\text{max}}$) in the fundamental diagram. This can also be verified for the modifications VDR and T$^2$ (Fig. 7). The small deviations from the data rest upon a difference between the outflow of the jam and the maximum global flow in the considered systems, but also in the above made assumption of the equilibrium. Actually, the lowered outflow from jams observed in the models VDR and T$^2$ in comparison to the SCA is also reflected by (8).

Concluding, this knowledge enables a calibration of the SCA. Besides the approach of the fundamental diagram derived from empirical data a further point of interest is the velocity of upstream moving jams ($\approx -15 \text{ km/h}$ on German highways [24]) – but according to [8] all information is accumulated in the fundamental diagram, namely in the second characteristic slope of $J(\rho)$. For the SCA one can set $v_{\text{max}} = 5$ and $p = 0.2 \cdots 0.3$ to adapt the simulation to this empirical jam velocity.

### IV. SUMMARY

We investigated the cellular automaton model for vehicular traffic in order to get information about the density waves and their velocity. Beside the standard Nagel-Schreckenberg cellular automata we also included two slow-to-start modifications (VDR and T$^2$). Both resemble the SCA except the rules for standing vehicles. Loosely spoken, they result in a lower flow downstream a jam and a clear phase separation for certain density regimes. For the determination of the jam velocity we used the density-autocorrelation function $C_{VJ}(r, \tau)$. Despite the high computational efforts ($O(L^2)$) this method was suitable to be applied for our calculations. Moreover, a definition of jams is not necessary and therefore the method can be applied to every model that provides density profiles along the road.
FIG. 7. The jam velocity can be explained by (8): \( V_J = \frac{J_{\text{max}}}{\rho_{\text{max}} - 1} \).
The quantity $C_{V_J}(r, \tau)$ reflects the two different phases and depends on the global density $\rho$. The density regime is separated by $\rho^*$. For $\rho < \rho^*$ no jams can be detected by the applied method, whereas for larger $\rho$ the system is dominated by sequences of dense and free-flow regions, where $C_{V_J}$ remains finite and permits to estimate $\rho^*$. At this point a transition to the congested region takes place. Both the local length $\lambda$ and the number of calculations $T$ have large influence on $C_{V_J}$. Further statements regarding the transition cannot be given due to the numerical insufficiencies and accuracy.

The jam velocity can be derived directly from $C_{V_J}(r, \tau)$. For sufficiently large $\rho$ the absolute value of $V_J$ is a continuous and descending function of $p$, but depends on the considered model. The differences between the models, especially for $p \to 0$ and $p \to 1$, could be explained by waiting time arguments. The jam velocity is essentially expressed through $\rho_{\text{max}}$ and $J_{\text{max}}$, irrespective of the model considered here.
