Abstract

In these lectures we introduce some of the principles and techniques that are relevant for the determination of the entropy of extremal black holes by either string theory or supergravity. We consider such black holes with $N = 2$ and $N = 4$ supersymmetry, explaining how agreement is obtained for both the terms that are leading and those that are subleading in the limit of large charges. We discuss the relevance of these results in the context of the more recent developments.

---

1 Based on lectures presented at the III Summer School in Modern Mathematical Physics, Zlatibor, 20 – 31 August, 2004.
1 Introduction

The aim of these lectures is to present a pedagogical introduction to recent developments in string theory and supergravity with regard to black hole entropy. In the last decade there have been many advances which have thoroughly changed our thinking about black hole entropy. Supersymmetry has been an indispensable ingredient in all of this, not just because it is an integral part of the theories we consider, but also because it serves as a tool to keep the calculations tractable. Comparisons between the macroscopic and the microscopic entropy, where the latter is defined as the logarithm of the degeneracy of microstates of a certain brane or string configuration, were first carried out in the limit of large charges, assuming the Bekenstein-Hawking area law on the macroscopic (supergravity) side. Later on also subleading corrections could be evaluated on both sides and were shown to be in agreement, although the area law ceases to hold. More recently these results have rekindled the interest in these questions and during the past year a variety of new developments took place.

We start with a brief exposition about the relation between black hole mechanics and thermodynamics. Then we review the connection between microscopic and macroscopic descriptions of black holes. As an example we discuss the situation for Calabi-Yau black holes, both from a microscopic and a macroscopic perspective. We elucidate the presence of subleading corrections, which, on the supergravity side originate from interactions with higher-order derivative terms. Subsequently we discuss heterotic black holes, where we extend the discussion to $N = 4$ supersymmetry introducing non-holomorphic corrections in order to preserve $S$-duality invariance. These results for $N = 4$ dyonic black holes are successfully confronted with a microscopic degeneracy formula. After a brief discussion of the $N = 4$ purely electric black holes and their relation to perturbative string states, we introduce the so-called mixed black hole partition function and discuss some of its consequences.

2 Black holes and thermodynamics

Black holes are, roughly speaking, solutions of Einstein’s equations of general relativity that exhibit an event horizon. From inside this horizon, nothing (and in particular, no light) can escape. In the context of this talk, it suffices to think of spherically symmetric and static black holes, with a flat space-time geometry at spatial infinity. By definition, the region inside the horizon is not in the backward lightcone of future timelike infinity. However, since the discovery of Hawking radiation it has become clear that many of the above classical features of black holes will have to be modified.

We will be considering black holes in four space-time dimensions, carrying electric and/or magnetic charges. Such solutions can be described by Einstein-Maxwell theory, the classical field theory for gravity and electromagnetism. The most general static black holes of this type correspond to the Reissner-Nordstrom solutions. They are characterized by a charge $Q$ and a mass $M$. In the presence of magnetic charges, $Q$ is replaced by $\sqrt{q^2 + p^2}$ in most
formulae, where \( q \) and \( p \) denote the electric and the magnetic charge, respectively. In this section there will therefore be no need to distinguish between the two types of charges. Note that without charges we will just be dealing with Schwarzschild black holes.

Two quantities associated with the black hole horizon are the area \( A \) and the surface gravity \( \kappa_s \). The area is simply the area of the two-sphere defined by the horizon. The surface gravity, which is constant on the horizon, is related to the force (measured at spatial infinity) that holds a unit test mass in place. The mass \( M \) and charge \( Q \) of the black hole are not directly associated with the horizon and can be expressed by appropriate surface integrals at spatial infinity.

As is well known, there exists a striking correspondence between the laws of thermodynamics and the laws of black hole mechanics \[1\]. Of particular importance is the first law, which, for thermodynamics, states that the variation of the total energy is equal to the temperature times the variation of the entropy, modulo work terms, for instance proportional to a change of the volume. The corresponding formula for black holes expresses how the variation of the black hole mass is related to the variation of the horizon area, up to work terms proportional to the variation of the angular momentum. In addition there can also be a term proportional to a variation of the charge, multiplied by the electric/magnetic potential \( \phi \) at the horizon. Specifically, the first law of thermodynamics, \( \delta E = T \delta S - p \delta V \), translates into

\[
\delta M = \frac{\kappa_s}{2\pi} \frac{\delta A}{4} + \phi \delta Q + \Omega \delta J .
\]

The reason for factorizing the first term on the right-hand side in this particular form, is that \( \kappa_s/2\pi \) represents precisely the Hawking temperature \[2\]. This then leads to the identification of the black hole entropy in terms of the horizon area,

\[
S_{\text{macro}} = \frac{1}{4} A ,
\]

a result that is known as the area law \[3\]. In these equations the various quantities have been defined in Planck units, meaning that they have been made dimensionless by multiplication with an appropriate power of Newton’s constant (we will set \( h = c = 1 \)). This constant appears in the Einstein-Hilbert Lagrangian according to \( L_{\text{EH}} = -(16\pi G_N)^{-1} \sqrt{|g|} R \). With this normalization the quantities appearing in the first law are independent of the scale of the metric.

Einstein-Maxwell theory can be naturally embedded into \( N = 2 \) supergravity which may lead to an extension with a variety of abelian gauge fields and a related number of massless scalar fields (often called ‘moduli’ fields, for reasons that will become clear later on). At spatial infinity these moduli fields will tend to a constant, and the black hole mass will depend on these constants, thus introducing additional terms on the right-hand side of \(1\).

For Schwarzschild black holes the only relevant parameter is the mass \( M \) and we note the following relations,

\[
A = 16\pi M^2 , \quad \kappa_s = \frac{1}{4M} ,
\]

consistent with \(1\). For the Reissner-Nordstrom black hole, the situation is more subtle. Here one distinguishes three different cases. For \( M > Q \) one has the non-extremal solutions, which
exhibit two horizons, an exterior event horizon and an interior horizon. When \( M = Q \) one is dealing with an extremal black hole, for which the two horizons coincide and the surface gravity vanishes. In that case one has

\[
A = 4\pi M^2, \quad \kappa_s = 0, \quad \phi = Q \sqrt{\frac{4\pi}{A}}.
\]

(4)

It is straightforward to verify that this result is consistent with (1) for variations in the subspace of extremal black holes (i.e., with \( \delta M = \delta Q \)). Because the surface gravity vanishes, one might expect the entropy to vanish as suggested by the third law of thermodynamics. Obviously, that is not the case as the horizon area remains finite for zero surface gravity. Finally, solutions with \( M < Q \) are not regarded as physically acceptable. Their total energy is less than the electromagnetic energy alone and they no longer have an event horizon but exhibit a naked singularity. Hence extremal black holes saturate the bound \( M \geq Q \) for physically acceptable black hole solutions.

When embedding Einstein-Maxwell theory into a complete supergravity theory, the above classification has an interpretation in terms of the supersymmetry algebra. This algebra has a central extension proportional to the black hole charge(s). Unitary representations of the supersymmetry algebra must necessarily have masses that are larger than or equal to the charge. When this bound is saturated, one is dealing with so-called BPS supermultiplets. Such supermultiplets are smaller than the generic massive \( N = 2 \) supermultiplets and have a different spin content. Because of this, BPS states are stable under (adiabatic) changes of the coupling constants, and the relation between charge and mass remains preserved. This important feature of BPS states will be relevant for what follows.

3 On macroscopic and microscopic descriptions

A central question in black hole physics concerns the statistical interpretation of the black hole entropy. String theory has provided new insights here [4], which have led to important results. In this context it is relevant that strings live in more than four space-time dimensions. In most situations the extra dimensions are compactified on some internal manifold \( X \) and one is dealing with the usual Kaluza-Klein scenario leading to effective field theories in four dimensions, describing low-mass modes of the fields associated with certain eigenfunctions on the internal manifold.

Hence the original space-time will locally be a product \( M^4 \times X \), where \( M^4 \) denotes the four-dimensional space-time that we experience in daily life. We will denote the coordinates of \( M^4 \) by \( x^\mu \) and those of \( X \) by \( y^{m} \). In the situation described above there exists a corresponding space \( X \) at every point \( x^\mu \) of \( M^4 \), whose size is such that it will not be directly observable. However, this space \( X \) does not have to be the same at every point in \( M^4 \), and moving through \( M^4 \) one may encounter various spaces \( X \) which may or may not be equivalent. Usually these spaces belong to some well-defined class of fixed topology parametrized by certain moduli. These moduli will appear as fields in the four-dimensional effective field theory. For instance, suppose that the spaces \( X \) are \( n \)-dimensional tori \( T^n \). The metric of \( T^n \) will appear as a field
in the four-dimensional theory and is related to the torus moduli. Hence, when dealing with a solution of the four-dimensional theory that is not constant in $M^4$, each patch in $M^4$ has a nontrivial image in the space of moduli that parametrize the internal spaces $X$.

Let us return to a black hole solution, viewed in this higher-dimensional perspective. Now the fields, and in particular the four-dimensional space-time metric, will vary nontrivially over $M^4$, and so will the internal space $X$. When moving to the center of the black hole the gravitational fields will become strong and the local product structure into $M^4 \times X$ could break down. Conventional Kaluza-Klein theory does not have much to say about what happens, beyond the fact that the four-dimensional solution can be lifted to the higher-dimensional one, at least in principle.

However, there is a feature of string theory that is absent in a purely field-theoretic approach. In the effective field-theoretic context only the local degrees of freedom of strings and branes are captured. But extended objects may also carry global degrees of freedom, as they can also wrap themselves around nontrivial cycles of the internal space $X$. This wrapping tends to take place at a particular position in $M^4$, so in the context of the four-dimensional effective field theory this will reflect itself as a pointlike object. This wrapped object is the string theory representation of the black hole!

We are thus dealing with two complementary pictures of the black hole. One based on general relativity where a point mass generates a global solution of space-time with strongly varying gravitational fields, which we shall refer to as the macroscopic description. The other one, based on the internal space where an extended object is entangled in one of its cycles, does not immediately involve gravitational fields and can easily be described in flat space-time. This description will be referred to as microscopic. To understand how these two descriptions are related is far from easy, but a connection must exist in view of the fact that gravitons are closed string states which interact with the wrapped branes. These interactions are governed by the string coupling constant $g_s$ and we are thus confronted with an interpolation in that coupling constant. In principle, such an interpolation is very difficult to carry out, so that a realistic comparison between microscopic and macroscopic results is usually impossible. However, reliable predictions are possible for extremal black holes! In a supersymmetric setting extremal black holes are BPS and, as we indicated earlier, in that situation there are reasons to trust such interpolations. Indeed, it has been shown that the predictions based on these two alternative descriptions can be successfully compared and new insights about black holes can be obtained.

But how do the wrapped strings and branes represent themselves in the effective action description and what governs their interactions with the low-mass fields? Here it is important to realize that the massless four-dimensional fields are associated with harmonic forms on $X$. Harmonic forms are in one-to-one correspondence with so-called cohomology groups consisting of equivalence classes of forms that are closed but not exact. The number of independent harmonic forms of a given degree is given by the so-called Betti numbers, which are fixed by the topology of the spaces $X$. When expanding fields in a Kaluza-Klein scenario, the number of corresponding massless fields can be deduced from an expansion in terms of tensors on
corresponding to the various harmonic forms. The higher-dimensional fields $\Phi(x, y)$ thus decompose into the massless fields $\phi^A(x)$ according to (schematically),

$$\Phi(x, y) = \phi^A(x) \omega_A(y),$$

where $\omega_A(y)$ denotes the independent harmonic forms on $X$. The above expression, when substituted into the action of the higher-dimensional theory, lead to interactions of the fields $\phi^A$ proportional to the ‘coupling constants’,

$$C_{ABC\ldots} \propto \int_X \omega_A \wedge \omega_B \wedge \omega_C \ldots.$$  

These constants are known as intersection numbers, for reasons that will become clear shortly.

We already mentioned that the Betti numbers depend on the topology of $X$. This is related to Poincaré duality, according to which cohomology classes are related to homology classes. The latter consist of submanifolds of $X$ without boundary that are themselves not a boundary of some other submanifold of $X$. This is precisely relevant for wrapped branes which indeed cover submanifolds of $X$, but are not themselves the boundary of a submanifold because otherwise the brane could collapse to a point. Without going into detail, this implies that there exists a dual relationship between harmonic $p$-forms $\omega$ and $(d_X - p)$-cycles, where $d_X$ denotes the dimension of $X$. We can therefore choose a homology basis for the $(d_X - p)$-cycles dual to the basis adopted for the $p$-forms. Denoting this basis by $\Omega_A$, the wrapping of an extended object can now be characterized by specifying its corresponding cycle $\mathcal{P}$ in terms of the homology basis,

$$\mathcal{P} = p^A \Omega_A.$$  

The integers $p^A$ count how many times the extended object is wrapped around the corresponding cycle, so we are actually dealing with integer-valued cohomology and homology. The wrapping numbers $p^A$ reflect themselves as magnetic charges in the effective action. The electric charges are already an integer part of the effective action, because they are associated with gauge transformations that usually originate from the higher-dimensional theory.

Owing to Poincaré duality it is thus very natural that the winding numbers interact with the massless modes in the form of magnetic charges, so that they can be incorporated in the effective action. Before closing this section, we note that, by Poincaré duality, we can express the number of intersections by

$$P \cdot P \cdot P \cdots = C_{ABC\ldots} p^A p^B p^C \cdots.$$  

This is a topological characterization of the wrapping, which will appear in later formulae.

## 4 Black holes in M/String Theory

As an example we now discuss the black hole entropy derived from both microscopic and macroscopic arguments in a special case. We start from M-theory, which, in the strong coupling limit of type-IIA string theory, is described by eleven-dimensional supergravity.
The latter is invariant under 32 supersymmetries. Seven of the eleven space-time dimensions are compactified on an internal space which is the product of a Calabi-Yau threefold (a three-dimensional complex manifold, which henceforth we denote by $CY_3$) times a circle $S^1$. Such a space breaks part of the supersymmetries and only 8 of them are left unaffected. In the context of the four-dimensional space-time $M^4$, these 8 supersymmetries are encoded into two independent Lorentz spinors and for that reason this symmetry is referred to as $N = 2$ supersymmetry. Hence the effective four-dimensional field theory will be some version of $N = 2$ supergravity.

M-theory contains a five-brane and this is the microscopic object that is responsible for the black holes that we consider; the five-brane has wrapped itself on a 4-cycle $P$ of the $CY_3$ space \[5\]. Alternatively one may consider this class of black holes in type-IIA string theory, with a 4-brane wrapping the 4-cycle \[6\]. The 4-cycle is subject to certain requirements which will be mentioned in due course.

The massless modes captured by the effective field theory correspond to harmonic forms on the $CY_3$ space; they do not depend on the $S^1$ coordinate. The 2-forms are of particular interest. In the effective theory they give rise to vector gauge fields $A^A_{\mu}$, which originate from the rank-three tensor gauge field in eleven dimensions. In addition there is an extra vector field $A^0_{\mu}$ corresponding to a 0-form which is related to the graviphoton associated with $S^1$. This field will couple to the electric charge $q_0$ associated with momentum modes on $S^1$ in the standard Kaluza-Klein fashion. The 2-forms are dual to 4-cycles and the wrapping of the five-brane is encoded in terms of the wrapping numbers $p^A$, which appear in the effective field theory as magnetic charges which couple to the gauge fields $A^A_{\mu}$. Here we see Poincaré duality at work, as the magnetic charges couple nicely to the corresponding gauge fields. For a Calabi-Yau three-fold, there is a triple intersection number $C_{ABC}$, which appears in the three-point couplings of the effective field theory. There is a subtle topological feature that we have not explained before, which is typical for complex manifolds containing 4-cycles, namely the existence of another quantity of topological interest known as the second Chern class. The second Chern class is a 4-form whose integral over a four-dimensional Euclidean space defines the instanton number. The 4-form can be integrated over the 4-cycle $P$ and yields $c_{2A} p^A$, where the $c_{2A}$ are integers.

Let us now turn to the microscopic counting of degrees of freedom \[5\]. These degrees of freedom are associated with the massless excitations of the wrapped five-brane characterized by the wrapping numbers $p^A$ on the 4-cycle. The 4-cycle $P$ must correspond to a holomorphically embedded complex submanifold in order to preserve 4 supersymmetries. The massless excitations of the five-brane are then described by a $(1+1)$-dimensional superconformal field theory (the reader may also consult \[7\]). Because we have compactified the spatial dimension on $S^1$, we are dealing with a closed string with left- and right-moving states. The 4 supersymmetries of the conformal field theory reside in one of these two sectors, say the right-handed one. Conformal theories in $1+1$ dimensions are characterized by a central charge, and in this case there is a central charge for the right- and for the left-moving sector separately. These central charges are expressible in terms of the wrapping numbers $p^A$ and depend on...
the intersection numbers and the second Chern class, according to
\[
c_L = C_{ABC} p^A p^B p^C + c_{2A} p^A, \\
c_R = C_{ABC} p^A p^B p^C + \frac{1}{2} c_{2A} p^A.
\]
We should stress that the above result is far from obvious and holds only under the condition that the \( p^A \) are large. In that case every generic deformation of \( \mathcal{P} \) will be smooth. Under these circumstances it is possible to relate the topological properties of the 4-cycle to the topological data of the Calabi-Yau space.

We can now choose a state of given momentum \( q_0 \) which is supersymmetric in the right-moving sector. From rather general arguments it follows that such states exist. The corresponding states in the left-moving sector have no bearing on the supersymmetry and these states have a certain degeneracy depending on the value of \( q_0 \). In this way we have a tower of BPS states invariant under 4 supersymmetries, built on supersymmetric states in the right-moving sector and comprising corresponding degenerate states in the left-moving sector. We can then use Cardy’s formula, which states that the degeneracy of states for fixed but large momentum (large as compared to \( c_L \)) equals \( \exp[2\pi \sqrt{|q_0| c_L / 6}] \). This leads to the following expression for the entropy,
\[
S_{\text{micro}}(p, q) = 2\pi \sqrt{\frac{1}{6} |\tilde{q}_0| (C_{ABC} p^A p^B p^C + c_{2A} p^A)},
\]
where \( q_0 \) has been shifted according to
\[
\tilde{q}_0 = q_0 + \frac{1}{2} C^{AB} q_A q_B.
\]
Here \( C^{AB} \) is the inverse of \( C_{AB} = C_{ABC} p^C \). This modification is related to the fact that the electric charges associated with the gauge fields \( A_\mu^A \) will interact with the M-theory two-brane \[5\]. The existence of this interaction can be inferred from the fact that the two-brane interacts with the rank-three tensor field in eleven dimensions, from which the vector gauge fields \( A_\mu^A \) originate.

We stress that the above results apply in the case of large charges. The first term proportional to the triple intersection number is obviously the leading contribution whereas the terms proportional to the second Chern class are subleading. The importance of the subleading terms will become more clear in later sections. Having obtained a microscopic representation of a BPS black hole, it now remains to make contact with it by deriving the corresponding black hole solution directly in the \( N = 2 \) supergravity theory. This is discussed in the next section.

5 Entropy formula for \( N = 2 \) supergravity

The charged black hole solutions in \( N = 2 \) supergravity are invariant under 4 of the 8 supersymmetries. They are solitonic, and interpolate between fully supersymmetric configurations at the horizon and at spatial infinity. At spatial infinity, where the effect of the charges
can be ignored, one has flat Minkowski space-time. The scalar moduli fields tend to certain (arbitrary) values on which the black hole mass will depend. At the horizon the situation is rather different, because here the charges are felt and one is not longer dealing with flat space-time, but with a so-called Bertotti-Robinson space, AdS$_2 \times S^2$. In that situation the requirement of full $N = 2$ supersymmetry is highly restrictive and for spherical geometries one can prove that the values of the moduli fields at the horizon are in fact fixed in terms of the charges. The corresponding equations are known as the attractor equations [8, 9, 10] and they apply quite generally. For effective actions with interactions quadratic in the curvature the validity of these attractor equations was established in [11].

The attractor equations play a crucial role as they ensure that the entropy, a quantity that is associated with the horizon, will depend on the black hole charges and not on other quantities, in line with the microscopic results presented in the previous section. Hence we are interested in studying charged black hole solutions which are BPS, meaning that they are invariant under 4 supersymmetries. The matter supermultiplets contain the gauge fields $A^A_\mu$ coupling to electric and magnetic charges $q_A$ and $p^A$, respectively. In addition there is one extra graviphoton field $A_\mu^0$ which may couple to charges $q_0$ and $p^0$. When comparing to the solutions of the previous section, we obviously will set $p^0 = 0$, but from the supergravity point of view there is no need for such a restriction.

However, there is an infinite variety of $N = 2$ supergravity actions coupling to vector multiplets. Fortunately these actions can be conveniently encoded into holomorphic functions that are homogeneous of second degree [12]. In the case at hand the simplest action is, for instance, based on the function,

$$F(Y) = \frac{1}{6} C_{ABC} Y^A Y^B Y^C,$$

where the holomorphic variables $Y^I$ ($I = 0, A$) are associated with the vector multiplets; they can be identified projectively with the scalar moduli fields that are related to a subset of the moduli of the Calabi-Yau space. The black hole solution will thus encode the changes in the Calabi-Yau manifold when moving from the black hole horizon towards spatial infinity, precisely as discussed in a more general context in section 3. Note the presence of the triple intersection form $C_{ABC}$ which will appear in the interaction vertices of the corresponding Lagrangian.

The attractor equations also involve the function $F(Y)$. In terms of the quantities $Y^I$ and the first derivatives of $F(Y)$, they take the form,

$$Y^I - \bar{Y}^I = ip^I, \quad F_I(Y) - \bar{F}_I(\bar{Y}) = iq_I,$$

where $F_I(Y) = \partial F(Y)/\partial Y^I$. In principle these equations yield the horizon values of the $Y^I$ in terms of the charges. Depending on the values of the charges and on the complexity of the function $F(Y)$, it may not be possible to write down solutions in closed form.

The action corresponding to (12) gives rise to a black hole solution with charges $p^A$, $q_A$ and $q_0$ (we take $p^0 = 0$). Its area can be calculated and is equal to

$$A(p, q) = 8\pi \sqrt{\frac{1}{4q_0} C_{ABC} p^A p^B p^C}.$$

(14)
Upon invoking the area law this result leads precisely to the first part of the microscopic entropy $F(Y)$. We have thus reproduced the leading contributions to the entropy from supergravity.

How can one reproduce the subleading terms in view of the fact that these terms scale differently whereas the function $F(Y)$ and the attractor equations all seem to scale uniformly? To explain how this is resolved we must first spend a few words on the reason why the function $F(Y)$ was homogeneous in the first place. The covariant fields corresponding to a vector supermultiplet comprise a so-called restricted chiral multiplet, which can be assigned a unique (complex) scaling weight. The $Y^I$ are proportional to the lowest component of these multiplets, and can be assigned the same scaling weight. Any (holomorphic) function of these restricted multiplets will define a chiral superfield, whose chiral superspace integral will lead to a supersymmetric action. However, in order to be able to couple to supergravity, this function must be homogeneous of second degree $[12]$. To deviate from this homogeneity pattern in the determination of the entropy, one needs to introduce a new type of chiral superfield whose value at the horizon will be fixed in a way that breaks the uniformity of the scaling. There exists such a multiplet. Namely, from the fields of (conformal) supergravity itself, one can again extract a restricted chiral multiplet, which in this case comprises the covariant quantities associated with the supergravity fields. This time the restricted chiral multiplet is not a scalar, but an auxiliary anti-selfdual tensor, and just as before it can be assigned a unique scaling weight. Its lowest component is an auxiliary field that is often called the graviphoton field strength, which is strictly speaking a misnomer because it never satisfies a Bianchi identity. It appears in the transformation rule of the gravitino fields and in simple Lagrangians its field equations express it in terms of moduli-dependent linear combinations of other vector field strengths. The square of this restricted tensor defines a complex scalar field which constitutes the lowest component of a chiral supermultiplet and which is proportional to a field we will denote by $\Upsilon$, such that the (complex) scaling weight that can be assigned to $\Upsilon$ is twice that of the $Y^I$. More general supergravity Lagrangians can then be described by holomorphic functions $F(Y, \Upsilon)$ that are homogeneous of degree 2, i.e.,

$$F(\lambda Y^I, \lambda^2 \Upsilon) = \lambda^2 F(Y^I, \Upsilon).$$

(15)

A nontrivial dependence on $\Upsilon$ in the function $F(Y, \Upsilon)$ has important consequences, because the supermultiplet of which $\Upsilon$ is the first component contains other components with terms quadratic in the Riemann tensor. Hence actions based on a function $[15]$ with a nontrivial dependence on $\Upsilon$ will contain terms proportional to the square of the Riemann tensor, multiplied by the first derivative of $F$ with respect to $\Upsilon$. The attractor equations remain valid with $F(Y')$ replaced by $F(Y, \Upsilon)$. However, the field $\Upsilon$ has its own independent attractor value; at the horizon it must be equal to $\Upsilon = -64$, independent of the charges. This phenomenon explains why the area and the entropy are not necessarily a homogeneous function of the charges.

To fully reproduce the entropy formula $[10]$ including the subleading terms proportional
to the second Chern class, one may attempt a Lagrangian based on the function
\[ F(Y) = -\frac{1}{6} \frac{C_{ABC} Y^A Y^B Y^C}{Y^0} - \frac{c_{2A}}{24 \cdot 64} \frac{Y^A \Upsilon}{Y^0}, \tag{16} \]
which is indeed holomorphic and homogeneous. On the basis of this modification one can again calculate the horizon area in the hope of recovering the entropy (14) upon use of the area law. However, the result is negative and it seems obvious that no solution can be found in this way [13].

At this point the only way out is to no longer rely on the area law in extracting a value for the entropy. Indeed the area law is not expected to hold for actions that supersede the Einstein-Hilbert one. Wald has proposed an alternative definition of black hole entropy which can be used for any Lagrangian that is invariant under general coordinate transformations, and which is based on the existence of a conserved surface charge [14]. The latter is related to the conventional Noether current associated with general coordinate transformations, which, for a gauge symmetry, can be written as a pure improvement term: the divergence of an antisymmetric tensor, called the Noether potential. It turns out that with the help of the Noether potential one can define a surface charge integrated over the boundary of a Cauchy surface, which for the black hole extends from spatial infinity down to the horizon. Changes in the continuous variety of black hole solutions should leave this charge unchanged. Under certain conditions one can show that the change of the surface integral at spatial infinity corresponds to the mass and angular momentum variations in the first law. Therefore one identifies the surface integral at the horizon with the entropy, so that the validity of the first law will remain ensured.

We should stress that there are various subtle points here, some of which have been discussed in [15]. The prescription based on the surface charge can be applied to standard Einstein gravity, in which case one just recovers the area law. But for theories with higher-derivatives, there are nontrivial correction terms, which follow from a calculation of the Noether potential. We should caution the reader that the relevant correction term in the case at hand does in fact not reside in the terms quadratic in the Riemann tensor, but in some other terms related to them by supersymmetry.

From an evaluation of the Noether potential, taking into account all the constraints imposed by the supersymmetry at the horizon, it follows that the entropy can be written in a universal form [16],
\[ S_{\text{macro}}(p, q) = \pi \left[ |Z|^2 - 256 \text{Im} F_Y \right]_{Y = -64}. \tag{17} \]
Here the first term denotes the Bekenstein-Hawking entropy, because $|Z|^2 = p^i F_i(Y, \Upsilon) - q_i Y^i$ is just the area in Planck units divided by $4\pi$. This term is clearly affected by the presence of the higher-order derivative interactions. On top of that there is a second term proportional to the derivative of $F(Y, \Upsilon)$ with respect to $\Upsilon$. This term thus represents the deviation of the area law. The above formula applies to any $N = 2$ supergravity solution.

Because of the fact that all quantities of interest are directly related to the holomorphic and homogeneous functions [15], the determination of the area and entropy is merely an
algebraic exercise, which no longer requires to construct the full solution. Given the function $F(Y, \Upsilon)$ one first attempts to solve the attractor equations (13), but now with $F_I(Y)$ replaced by $F_I(Y, \Upsilon)$. Subsequently one determines the area and the entropy in terms of the charges. For the function (16) this was shown to lead precisely to the microscopic entropy formula (10). To exhibit the deviation from the area law, we also give the area (which is obviously not known from microscopic considerations),

$$\frac{1}{4} A(p, q) = \frac{C_{A B C} p^A p^B p^C + \frac{1}{2} c_{2A} p^A}{C_{A B C} p^A p^B p^C + c_{2A} p^A} S_{\text{macro}}(p, q).$$

Interestingly the proportionality factor is just the ratio $c_R/c_L$ of the two central charges defined in (10). By combining new ingredients from supergravity and general relativity it is thus possible to fully account for the black hole entropy that is obtained by counting microstates.

Before moving to the next section we wish to add some observations. In addition to being able to evaluate the properties of the black hole solution at the horizon one should also like to understand the full structure of the BPS black holes away from the horizon, in the presence of the interactions quadratic in the Riemann curvature. This was the subject of [11], where a rather general class of such solutions was studied, including multi-centered ones. We refer to that work for further details. It is also worth pointing out that we have always been basing ourselves on the effective Wilsonian action. A priori, one does not expect that the final macroscopic description of black hole mechanics can be obtained exclusively within a Wilsonian framework.

6  Heterotic black holes

In [15, 17] the modified entropy formula (17) was applied to heterotic black holes. Although the formula is derived for $N = 2$ supergravity, the result can readily be generalized to the case of heterotic $N = 4$ supersymmetric compactifications. This involves an extension of the target-space duality group to $\text{SO}(6,22)$ with a corresponding extension to 28 electric and 28 magnetic charges that take their values in a $\Gamma_{6,22}$ lattice. The $N = 4$ supersymmetric heterotic models have dual realizations as type-II string compactifications on $K3 \times T^2$. In contrast to $N = 2$ Calabi-Yau compactifications, the holomorphic function which encodes the effective Wilsonian action is severely restricted in the $N = 4$ case. Therefore it is often possible to obtain exact predictions in this context.

The relevant function for the heterotic case takes the following form in lowest order,

$$F(Y) = -\frac{Y^1 Y^a \eta_{ab} Y^b}{Y^0},$$

where $a, b = 2, \ldots, n$. This function will be modified in due course by a function of $\Upsilon$ and of the dilaton field $S = -i Y^1/Y^0$. Let us first consider (19) in the absence of these modifications. Then the $2n$ scalar moduli in the effective action are described by a nonlinear sigma model
with the following target space,

\[ \mathcal{M} = \frac{SU(1,1)}{U(1)} \times \frac{SO(2,n-1)}{SO(2) \times SO(n-1)}. \]  

(20)

The electric and magnetic charges transform under the action of the \( SU(1,1) \times SO(2,n-1) \) isometry group. The first factor, \( SU(1,1) \), is associated with \( S \)-duality. This is a strong-weak coupling duality which interchanges electric and magnetic charges. The second factor, \( SO(2,n-1) \), is associated with \( T \)-duality (also called target-space duality). There is a technical complication in the description based on (19) because the charges that follow from the \( Y^I \) through the attractor equations are not in a convenient basis for \( S \)- and \( T \)-duality. A proper basis is found upon interchanging the electric and magnetic charges \( q_1 \) and \( p_1 \) by an electric/magnetic duality. Fortunately there is no need to discuss this in any detail, as the entropy and area of the corresponding black holes depend only on \( T \)-duality invariants of the charges. Note that in the extension to \( N = 4 \) the second factor of the target space (20) changes into \( SO(6,22)/[SO(6) \times SO(22)] \); this space is parametrized by the 132 scalar fields belonging to 22 \( N = 4 \) vector supermultiplets.

To be specific let us first quote the result for the entropy and horizon area for the solution based on (19) as a function of the charges,

\[ S_{\text{macro}}(p, q) = \frac{1}{4} A(p, q) = \pi \sqrt{q_0^2 p_0^2 - (p \cdot q)^2}. \]  

(21)

Here we used \( T \)-duality invariant combinations of the charges, defined by

\[ q^2 = 2 q_0 p^1 - \frac{1}{2} q_0 q_1, \]
\[ p^2 = -2 p_0^0 q_1 - 2 p_0^a \eta_{ab} p^b, \]
\[ p \cdot q = q_0 p_0^0 - q_1 p_1^1 + q_a p^a, \]  

(22)

where the \( p^I \) and \( q_I \) on the right-hand side are the charges that appear in the attractor equations (13) based on the function (19). While the combinations (22) are invariant under \( T \)-duality, they transform as an \( SO(2,1) \) vector under \( S \)-duality, such that the entropy formula (21) is invariant under both \( T \)- and \( S \)-duality. The \( S \)-duality transformations, which constitute the group \( SL(2, \mathbb{Z}) \), of the charges and of the dilaton field are related through the attractor equations. They are given by

\[ S \rightarrow a S - ib, \]
\[ q^2 \rightarrow a^2 q^2 + b^2 p^2 + 2 ab p \cdot q, \]
\[ p^2 \rightarrow c^2 q^2 + d^2 p^2 + 2 cd p \cdot q, \]
\[ p \cdot q \rightarrow ac q^2 + bd p^2 + (ad + bc) p \cdot q, \]  

(23)

with integer-valued parameters \( a, b, c, d \) satisfying \( ad - bc = 1 \). In the \( N = 4 \) theory, the charge lattice is \( S \)-duality invariant, meaning that the above transformations always lead to a point on the lattice that is physically realized. Note that the supergravity calculations yield no intrinsic definition of the normalization of the charge lattice and consequently the dilaton
normalization is a priori not known. Hence the precise characterization of the arithmetic subgroup of SL(2) that defines the S-duality group is not obvious, but the crucial point is that the normalization of the dilaton is related to the normalization of the lattice of charges. Later on in this section we will relate the supergravity results to microscopic data which will confirm the above identifications. Observe that the invariants \( p^2 \) and \( q^2 \) are not positive definite. In fact in the limit of large charges they will both become negative.

When adding a function to (19) proportional to \( \Upsilon \) and depending otherwise on the dilaton field \( S \), it turns out that the target-space duality remains unaffected. However, \( S \)-duality is affected in general so the question is whether there exists a specific modification that leaves \( S \)-duality intact. This turns out to be the case, but one is forced to accept a certain amount of non-holomorphicity in the description [17]. To derive this is rather nontrivial and we simply quote the result in a form that was indicated in [18],

\[
F(Y, \bar{Y}, \Upsilon, \bar{\Upsilon}) = -\frac{Y^a Y^b}{Y_0} \frac{1}{64\pi} \Upsilon \log \eta^{12}(S) + \frac{i}{128\pi} (\Upsilon + \bar{\Upsilon}) \log(S + \bar{S})^6 ,
\]

where the non-holomorphic corrections reside in the last term. For the convenience of the reader we define the Dedekind eta-function,

\[
\eta(q_r) = q_r^{1/24} \prod_{n=1}^{\infty} (1 - q_r^n) ,
\]

where \( q_r = \exp(2\pi i \tau) \). It satisfies the asymptotic formula, \( \ln \eta(q_r) = \frac{1}{2\pi} \ln q_r - \frac{3}{8} q_r^2 - \frac{4}{3} q_r^3 - \frac{7}{4} q_r^5 + O(q_r^6) \). By \( \eta(S) \) we mean \( \eta(q_r) \) with \( \tau = i S \), so that \( \log \eta(S) \approx -\frac{1}{12\pi} S - e^{-2\pi S} + O(e^{-10\pi S}) \). We also recall that \( \eta^{24}(S) \) is a modular form of degree 12, so that \( \eta^{24}(S') = (icS + d)^{12} \eta^{24}(S) \), where \( S' \) is the transformed dilaton field as defined in [23].

The presence of non-holomorphic terms in (24) is not entirely unexpected: the Wilsonian couplings are holomorphic but may not fully reflect the symmetries of the underlying theory, while the physical couplings must reflect the symmetry and may thus have different analyticity properties. The non-holomorphic terms are determined uniquely by requiring \( S \)-duality and consistency with string perturbation theory, and are in accord with the \( N = 4 \) results of [19]. The normalization of the new terms is, however, not fixed by \( S \)-duality. It has been fixed by using string-string duality, or, alternatively, by requiring agreement with the known asymptotic degeneracy of electrically charged black holes, as we shall see later on.

Including the non-holomorphic corrections, the result of [17] can be summarized as follows. The non-trivial attractor equations are the ones that determine the horizon value of the complex dilaton field \( S \) in terms of the black hole charges. They read as follows (we have now set \( \Upsilon \) to its horizon value),

\[
|S|^2 p^2 = q^2 - \frac{2}{\pi} (S + \bar{S}) \left( S \frac{\partial}{\partial S} + \bar{S} \frac{\partial}{\partial \bar{S}} \right) \log \left[ (S + \bar{S})^6 \eta(S)^{24} \right] ,
\]

\[
(S - \bar{S}) p^2 = -2i p \cdot q + \frac{2}{\pi} (S + \bar{S}) \left( \frac{\partial}{\partial S} - \frac{\partial}{\partial \bar{S}} \right) \log \left[ (S + \bar{S})^6 \eta(S)^{24} \right] .
\]

The expression for the macroscopic entropy reads,

\[
S_{\text{macro}} = -\pi \left[ \frac{q^2 - ip \cdot q (S - \bar{S}) + p^2 |S|^2}{S + \bar{S}} \right] - 2 \log \left[ (S + \bar{S})^6 \eta(S)^{24} \right] ,
\]
with the dilaton field subject to (26). The first term in this equation corresponds to one-fourth of the horizon area, which, via (26), is affected by the various corrections. The second term represents an extra modification, which explicitly contains the non-holomorphic correction. Both terms are invariant under target-space duality and $S$-duality. As explained above, $S$-duality was achieved at the price of including non-holomorphic terms, here residing in the $\log(S + \bar{S})$ terms.

In string perturbation theory the real part of $S$ becomes large and positive, and one can neglect the exponential terms of the Dedekind eta-function. In that approximation the imaginary part of $S$ equals $\text{Im } S = -p \cdot q / p^2$ and the real part is determined by a quadratic equation,

$$\frac{1}{4} p^2 (p^2 - 8) (S + \bar{S})^2 + \frac{12}{\pi} p^2 (S + \bar{S}) = q^2 p^2 - (p \cdot q)^2.$$  

(28)

Obviously, these perturbative results are affected by the presence of the non-holomorphic corrections. Using (28), we find the following expression for the corresponding entropy,

$$S_{\text{macro}} = -2\pi \left[ \frac{q^2 p^2 - (p \cdot q)^2}{p^2 (S + \bar{S})} \right] - 12 \left[ \log(S + \bar{S}) - 1 \right].$$  

(29)

For large charges and finite value of $S$, the above result for $S_{\text{macro}}$ tends to (21).

In the $N = 4$ setting one can distinguish two types of BPS-states. Purely electric or magnetic configurations constitute $1/2$-BPS states, whereas dyonic ones are $1/4$-BPS states. For $N = 2$ the distinction between the two types of states disappears and one has only $1/2$-BPS states. In the context of $N = 4$, the generic BPS states are the dyonic ones, characterized by a nonzero value for $q^2 p^2 - (p \cdot q)^2$. Actually, the $S$-duality invariant characterization of the $1/2$-BPS states, is precisely expressed by the condition $q^2 p^2 - (p \cdot q)^2 = 0$. In the remainder of this section we restrict our attention to the dyonic states. The macroscopic results given above can be confronted with an explicit formula for the microscopic degeneracy of BPS dyons in four-dimensional $N = 4$ string theory proposed in [20]. This proposal generalizes the expression for the degeneracies of electric heterotic string states (to be presented in the next section), to an expression that depends on both electric and magnetic charges such that it is formally covariant with respect to $S$-duality. In [20] it was already shown that the dyonic degeneracy was consistent with the area law, i.e. with (21) in the limit of large charges.

Let us be a little more specific about the actual degeneracy formula. It is expressed in terms of an integral over an appropriate 3-cycle that involves an automorphic form $\Phi_{10}(\Omega)$,

$$d(q, p) = \oint d\Omega \frac{e^{i\pi(Q^T \Omega Q)}}{\Phi_{10}(\Omega)}.$$  

(30)

Here $\Omega$ denotes the period matrix for a genus-2 Riemann surface, which parametrizes the $\text{Sp}(2)/\text{U}(2)$ cosets; it can be written as a complex, symmetric, two-by-two matrix,

$$\Omega = \begin{pmatrix} \rho & v \\ v & \sigma \end{pmatrix}.$$  

(31)

In the exponent of the numerator of (30) the direct product of the period matrix with the invariant metric of the charge lattice is contracted with the charge vector comprising the 28
magnetic and 28 electric charges, so that \( Q^T \Omega Q = \rho p^2 + \sigma q^2 + 2 v p \cdot q \), where \( p^2, q^2 \) and \( p \cdot q \) were defined previously in (22). A representation of \( \Phi_{10} \) in the form of a Fourier series with three complex arguments is, for instance, given in (32).

\[
\Phi_{10}(\Omega) = q_\rho q_\sigma q_v \prod_{\{k,l,m\}} (1 - q_\rho^k q_\sigma^l q_v^m)^c(k,l,m),
\]

where \( q_\rho = \exp(2\pi i \rho) \), \( q_\sigma = \exp(2\pi i \sigma) \) and \( q_v = \exp(2\pi i v) \). Some more details can be found in [18]. The inverse of \( \Phi_{10} \) has poles and the formula (30) picks up a corresponding residue whenever the 3-cycle encloses such a pole. However, the poles are located in the interior of the Siegel half-space and not just at its boundary and therefore the choice of the 3-cycles is subtle.

In [18] the degeneracy formula was studied by means of a saddle-point approximation in the limit of large charges, but now retaining also the terms that are subleading. Remarkably enough the result is in precise agreement with the macroscopic results, i.e. with (26) and (27), including the non-holomorphic terms. The equations (26) turn out to correspond to the equations that determine the location of the saddle-point, while (27) represents the value of the integrand in (30) taken at the saddle-point, including the contribution from integrating out the fluctuations about the saddle-point. This shows that the macroscopic entropy, defined by (27) as a function of the charges and the dilaton field, is in fact stationary under variations of the latter. In fact, it is possible to understand this stationarity principle on the basis of the variational principle proposed in [22], upon a proper extension with \( \Upsilon \)-dependent terms and non-holomorphic corrections.

### 7 The area law and elementary string states

The area law is clearly violated in the presence of the subleading corrections, as is shown in the \( N = 2 \) entropy formula (17). Of course, it depends on the theory in question and on the values for the charges, how sizable this violation is. A particularly interesting case emerges for black holes for which the leading contribution to the entropy and area vanish. In that case, the subleading terms become dominant and (18) shows that the area law is replaced by \( S_{\text{macro}} = \frac{1}{2} A(p, q) \), whereas the typical dependence on the charges proportional to the square root of a quartic polynomial is changed into the square root of a quadratic polynomial. It is easy to see how this can be accomplished for the heterotic black holes, namely, by suppressing all the charges in (22) with the exception of \( q_0 \) and \( p^1 \), leading to \( q^2 \) as the only nonvanishing \( T \)-duality invariant charge combination. This is a remarkable result. In fact these states are precisely generated by perturbative heterotic string states arising from a compactification of six dimensions. In the supersymmetric right-moving sector they carry only momentum and winding and contain no oscillations, whereas in the left-moving sector oscillations are allowed that satisfy the string matching condition. The oscillator number is then linearly related to \( q^2 \). These string states are 1/2-BPS states and correspond to electrically charged states (possibly upon a suitable electric/magnetic duality redefinition).
Precisely these perturbative states already received quite some attention in the past (for an early reference, see [23]). Because the higher-mass string BPS states are expected to be within their Schwarzschild radius, it was conjectured that they should have an interpretation as black holes.\(^1\) Their calculable level density, proportional to the exponent of \(4\pi \sqrt{|q^2|}/2\), implies a nonzero microscopic entropy for these black holes [24]. On the other hand the corresponding black hole solutions were constructed in [25, 26] and it was found that their horizon area vanishes, which, on the basis of the area law, would imply a vanishing macroscopic entropy.

Of course, higher-order string corrections are expected to modify the situation at the horizon. One of the ways to incorporate their effect is to make use of the concept of a ‘stretched’ horizon, a surface close to the event horizon whose location is carefully adapted in order that the calculations remain internally consistent. In this way it is possible to reconcile the non-zero level density with the vanishing of the classical horizon area [26, 27], although the precise proportionality factor in front of \(\sqrt{|q^2|}/2\) cannot be determined.

On the other hand, these corrections will undoubtedly be related to interactions of higher order in the curvature tensor whose effect can be studied in the context of the modified entropy formula (17) together with the attractor equations (after all, their derivation did not pose any restriction on the values of the leading contributions to area and entropy). In fact, some of the results can be read off easily from the formulae (26) and (27). They show that the dilaton field becomes large and real (in contrast with the dyonic case, where the dilaton could remain finite and complex). Direct substitution yields,

\[
S + \bar{S} \approx \sqrt{|q^2|}/2, \\
S_{\text{macro}} \approx 4\pi \sqrt{|q^2|}/2 - 6 \log |q^2|,
\]

where the logarithmic term is due to the non-holomorphic contribution. Because the dilaton is large in this case, all the exponentials in the Dedekind eta-function are suppressed and we are at weak string coupling. Consequently the formalism discussed in section 5 yields the expected results. In fact, without the non-holomorphic corrections the result for the entropy can be obtained directly from (10), upon taking \(q_0 = q_0, C_{ABC} = 0\) and \(c_2^4 p^4 = 24 p^4\).

Not much attention was paid to this particular application of (17) until recently, when attention focused again on the electric black holes [28], this time primarily motivated by a reformulation of the black hole entropy (17) in terms of a mixed partition function [29]. We turn to the latter topic in the next section. The observation that (17) can nicely account for the discrepancies encountered in the classical description of the 1/2-BPS black holes was first made in [28, 30]. Note also that, since the electric states correspond to perturbative heterotic string states, their degeneracy is known from string theory and given by

\[
d(q) = \oint d\sigma \frac{e^{i\pi q^2}}{\eta^{24}(\sigma)} \approx \exp \left(4\pi \sqrt{|q^2|}/2 - \frac{27}{4} \log |q^2|\right),
\]

where the integration contour encircles the point \(\exp(2\pi i \sigma) = 0\). The large-\(|q^2|\) approximation

\(^1\)The idea that elementary particles, or string states, are behaving like black holes, has been around for quite some time. However, it is outside the scope of these lectures to discuss this in more detail.
is based on a standard saddle-point approximation. Obviously the leading term of (34) is in agreement with (33). However, the logarithmic corrections carry different coefficients.

At this point we should recall that the dyonic degeneracy formula (30) was proposed at the time \[20\] as an $S$-duality invariant extension of the electric degeneracy formula (34). While for the dyonic states the macroscopic results agree fully with the results obtained from a saddle-point approximation of (30), we conclude that the situation regarding the electric states is apparently more subtle. We refrain from discussing this in more detail.

Recently, there have been quite a number of papers about the electric black holes, discussing the effect of the higher-derivative corrections in the effective action on the horizon behaviour and on more global aspects of the black hole solutions \[31, 32, 33, 34\]; two of them also discuss the effect of the non-holomorphic corrections \[31, 34\]. Other papers are pursuing the consequences of the conjecture of \[29\], where a mixed black hole partition function is proposed proportional to the square of the topological string partition function \[28, 35\]. We turn to a discussion of this partition function and some of its consequences in the next section.

8 A black hole partition function

The attractor equations \[8, 9, 10\] were originally interpreted as the conditions that extremized the central charge (i.e., the so-called BPS charge $Z$, as at the horizon there is full supersymmetry so that the supersymmetry algebra will not exhibit a central charge). Subsequently a variational principle was written down in \[22\] for some ‘potential’ $V$, which was indeed stationary whenever the attractor equations were satisfied; at the stationary point $V$ was precisely equal to the macroscopic entropy (up to some normalization). This variational principle did not receive much attention, but it recently it re-emerged in the work of \[36\]. Meanwhile, in a separate development, another variational principle had been introduced \[29\], and furthermore, as we already noted at the end of section 6 the attractor equations and the entropy for heterotic black holes, expressed in terms of the charges and the dilaton field, seem to be based on an underlying variational principle. It is unlikely that all these variational principles are unrelated, and indeed one can prove that the variational principle of \[22\] can yield these other variational principles upon solving a consistent subset of the extremality conditions. In some cases, this obviously requires a proper extension of $V$ with $T$-dependent terms and/or non-holomorphic corrections.

In the proposal of \[29\] the magnetic attractor equations are imposed, so that the $Y^I$ are expressed in terms of the magnetic charges $p^I$ and (real) electrostatic potentials $\phi^I$ at the horizon,

$$Y^I = \frac{\phi^I}{2\pi} + \frac{ip^I}{2}. \quad (35)$$

The electric attractor equations will then follow from a variational principle associated with
variations of the $\phi^I$ and the result was written in the form,

$$S_{\text{macro}}(p, q) = F(\phi, p) - \phi^I \frac{\partial F(\phi, p)}{\partial \phi^I},$$

$$q_I = \frac{\partial F(\phi, p)}{\partial \phi^I},$$

where the real function $F(\phi, p)$ is defined by

$$F(\phi, p) = 4\pi \text{Im}[F(Y, \Upsilon)]|_{\Upsilon = -64}.$$  

In [18] it was shown how to incorporate non-holomorphic corrections into the function $F(\phi, p)$. The result (36) shows that the function $F(\phi, p)$ and the entropy $S_{\text{macro}}(p, q)$ are related by a Legendre transform, which suggests the introduction of a mixed black hole partition function, $Z_{\text{BH}}(\phi, p)$, defined by

$$e^{F(\phi, p)} = Z_{\text{BH}}(\phi, p) = \sum_{\{q_I\}} d(q, p) e^{q_I \phi_I},$$

where the $d(q, p)$ are the microscopic black hole degeneracies. This partition function is a mixed partition function, as it treats the electric and the magnetic charges differently: with respect to the magnetic charges one is dealing with a microcanonical ensemble and with respect to the electric charges one has a canonical ensemble. Note that the left-hand side of (38) can be written as the modulus square of $\exp[-2\pi i F(Y, \Upsilon)]$, where the $Y^I$ are given by (35) and $\Upsilon = -64$. The holomorphic expression $\exp[-2\pi i F(Y, \Upsilon)]$ is actually related to the partition function for the topological string; the non-holomorphic corrections, which we suppressed here, are related to the so-called holomorphic anomaly [37]. The connection with topological string theory was further discussed in [38, 36].

The equation (38) implies that the black hole degeneracies can be expressed as a Laplace transform of the partition function $Z_{\text{BH}}(\phi, p)$ [29],

$$d(q, p) \sim \int \prod_I d\phi^I \left| e^{-2\pi i F(Y, \Upsilon)} \right|^2 e^{-q_I \phi_I}.$$  

where the $Y^I$ are still given by (35) and $\Upsilon = -64$. For large values of the $q_I$ the Laplace transform can be solved by a saddle-point approximation which leads to the exponent of entropy $S_{\text{macro}}(p, q)$ in accord with (36).

One should be aware that there are, however, many subtleties with these expressions (see, for instance, [35] where some of these are discussed). One of them which we would like to mention, is related to electric/magnetic duality. The attractor equations (13) and the expression for the macroscopic entropy (17) are manifestly consistent with this duality. This means that, for instance, the expression for the entropy transforms as a scalar function and its expression in a dual description is simply obtained by applying the duality on the charges $p^I$ and $q_I$, i.e., $S'_{\text{macro}}(p', q') = S_{\text{macro}}(p, q)$. This implies, in particular, that the entropy will be invariant under a subgroup of the electric/magnetic duality group that constitutes an invariance. The same property applies presumably also for the microscopic black hole
degeneracies, $d(q,p)^2$. On the other hand, the mixed partition function and the functions $F(Y,\Upsilon)$ and $\mathcal{F}(\phi,p)$ do not transform as functions under electric/magnetic duality; this is already obvious from the fact that the $(p^I,\phi^I)$ do not transform simply under this duality, unlike $(p^I,q_I)$. This aspect is, of course, relevant when giving a more precise meaning to equations such as (38) and (39).

These subtle issues are, however, outside the scope of these lectures, which are aimed at providing a pedagogical introduction and overview of relatively recent results pertaining to the determination of the black hole entropy in string theory and supergravity and their relation. Interested readers are advised to consult the literature for further information.

Most of my own work on the topic of these lectures has been in collaboration with Gabriel Lopes Cardoso, Jürg Käppeli and Thomas Mohaupt, whom I thank for their valuable comments on the text. This work is partly supported by EU contract MRTN-CT-2004-005104.

---

2This is demonstrated for the case of heterotic black holes, where both the macroscopic and the microscopic description are invariant under $S$-duality. The application of more general dualities may be more subtle, however, as this particular example is outside the restricted context of the Wilsonian action.
