First Observation of the Decays $B^0 \to D^*-p\bar{p}\pi^+$ and $B^0 \to D^*-p\bar{n}$

CLEO Collaboration

(November 28, 2021)

Abstract

We report the first observation of exclusive decays of the type $B \to D^*N\bar{N}X$, where $N$ is a nucleon. Using a sample of $9.7 \times 10^6 B\bar{B}$ pairs collected with the CLEO detector operating at the Cornell Electron Storage Ring, we measure the branching fractions $B(B^0 \to D^*-p\bar{p}\pi^+) = (6.5^{+1.3}_{-1.2} \pm 1.0) \times 10^{-4}$ and $B(B^0 \to D^*-p\bar{n}) = (14.5^{+3.4}_{-3.0} \pm 2.7) \times 10^{-4}$. Antineutrons are identified by their annihilation in the CsI electromagnetic calorimeter.

A unique feature of the $B$ meson system is that the large mass of the b-quark allows for
many of the weak decays of the $B$ meson to include the creation of a baryon-antibaryon pair.
In the simplest picture, baryons are expected to be produced in decays of the type $B \rightarrow \bar{X}_c p X$, and it has been only decays of this type which have been exclusively reconstructed
to date \cite{1}. However, one can combine the recently measured value $\mathcal{B}(\Lambda_c^+ \rightarrow pK^-\pi^+)$ =
$(5.0 \pm 0.5 \pm 1.2)\%$ \cite{2} with estimates of the product branching fraction $\mathcal{B}(B \rightarrow \Lambda_c X) \times \mathcal{B}(\Lambda_c \rightarrow pK^-\pi^+)$ of $(1.81 \pm 0.22 \pm 0.24) \times 10^{-3}$ \cite{3} to determine that $B \rightarrow \bar{\Lambda}_c N X$ modes, where $N$
is a proton or a neutron, account for only about half of the total $B \rightarrow Baryons$ rate.
Dunietz \cite{4} has suggested that modes of the type $B \rightarrow D^* N X$, in which $D$ represents any
charmed meson, are likely to be sizeable. $B \rightarrow D N N X$ final states can arise from either
the hadronization of the $W$ boson into a baryon-antibaryon pair, or the production of a
highly excited charmed baryon which decays strongly into a baryon plus a charmed meson.
CLEO has previously reported an inclusive upper limit for $\mathcal{B}(B \rightarrow D N N X)$ of $< 4.8 \%$ at
90% confidence level \cite{5}. We report the first observation of decays of this type, and present
measurements of the branching fractions $\mathcal{B}(B^0 \rightarrow D^{*-} p \bar{\pi}^+) \text{ and } \mathcal{B}(\bar{B}^0 \rightarrow D^{*-} p \bar{n})$. The charge
conjugate process is implied in the reconstruction of $B^0 \rightarrow D^{*-} p \bar{\pi}^+$. However,
in the reconstruction of $B^0 \rightarrow D^{*-} p \bar{n}$ only the mode with the antineutron is used in our
measurement because neutrons do not have a distinctive annihilation signature in the CLEO
detector.

The data were taken with the CLEO II detector \cite{6} at the Cornell Electron Storage Ring
(CESR). The sample we use corresponds to an integrated luminosity of 9.1 fb$^{-1}$ from data
taken on the $\Upsilon(4S)$ resonance, corresponding to $9.7 \times 10^6 B \bar{B}$ pairs, and 4.5 fb$^{-1}$ in the
continuum at energies just below the $\Upsilon(4S)$. We assume that 50% of the $B \bar{B}$ pairs consist of
$B^0 \bar{B}^0$, and that there are equal numbers of $B^0$ and $\bar{B}^0$ mesons. Charged particle trajectories
are measured in a cylindrical drift chamber operating in a 1.5 T magnetic field. Photons and
antineutrons are detected using an calorimeter consisting of 7800 CsI crystals with excellent
resolution in position and electromagnetic shower energy. Simulated events were generated
with a GEANT-based Monte Carlo program \cite{7}. Sixty percent of the data were taken in the
CLEO II.V configuration \cite{8}.

Charged particle identification is accomplished by combining the specific ionization
(dE/dx) measurements from the drift chamber with time-of-flight (TOF) scintillation
counter measurements. We reconstruct the decay mode $D^{*-} \rightarrow D^0\pi^-$, with $D^0 \rightarrow K^+\pi^-$,
$\bar{D}^0 \rightarrow K^+\pi^-\pi^0$, and $\bar{D}^0 \rightarrow K^+\pi^-\pi^+\pi^-$. Pairs of calorimeter showers with photon-like lateral
shower shapes and invariant mass within 2.5 standard deviations of $M(\pi^0)$ are considered as
$\pi^0$ candidates. We select $D^{*-}$ candidates using 95% efficient cuts around the central values
of the $M_{D^0}$ and $(M_{D^*-} - M_{D^0})$ distributions. In the few cases where there is more than one $D^*$
candidate in an event, the candidate which is closest to $M_{D^0} = 1.8646$ GeV and $(M_{D^*-} - M_{D^0})$
= 0.1454 GeV \cite{9} is chosen.

To reconstruct $B^0$ candidates for $B^0 \rightarrow D^{*-} p \bar{\pi}^+$, we calculate the beam constrained
mass, $M(B) \equiv \sqrt{E_{\text{beam}}^2 - p(B)^2}$, where $E_{\text{beam}}$ is the beam energy, and $p(B)$ is the $B^0$
candidate three-momentum magnitude. We also use the energy difference between the beam
energy and the energy of the reconstructed $B$ candidate: $\Delta E \equiv E_{\text{beam}} - E(B)$. Using a
Monte Carlo simulation program, we find the detector resolution for the $\Delta E$ distribution for
each $D^0$ mode, and require that the measured $\Delta E$ is within 3 standard deviations of zero.

The $M(B)$ resolution is dominated by the beam energy spread and is consistent with the

4
Monte Carlo simulation for $B^0 \to D^{*-} p \bar{p} \pi^+$, which predicts it to be Gaussian with a width of $\sigma = 2.7$ MeV. The $M(B)$ distribution is fitted to a Gaussian function with the predicted width, and a polynomial background function with suppression at the $E_{\text{beam}}$ threshold. The fitted signal yield is $32.3^{+6.3}_{-6.0}$ events, where the errors are statistical only. If $\sigma$ is allowed to float, a value of $\sigma = 2.1 \pm 0.4$ MeV is obtained, consistent with the Monte Carlo prediction. Figure 1 shows $\Delta E$ vs $M(B)$ for $B^0 \to D^{*-} p \bar{p} \pi^+$, and Figure 2(a) shows $M(B)$ for $B^0 \to D^{*-} p \bar{p} \pi^+$.

![Figure 1](image1.png)

**FIG. 1.** $\Delta E$ vs $M(B)$ distribution for $B^0 \to D^{*-} p \bar{p} \pi^+$. The solid circles indicate events in the signal region.

![Figure 2](image2.png)

**FIG. 2.** $M(B)$ distribution for (a) $B^0 \to D^{*-} p \bar{p} \pi^+$ and (b) $B^0 \to D^{*-} p \bar{n}$. Each plot is fitted to the sum of a background function and a fixed-width Gaussian signal shape.

To find the decay $B^0 \to D^{*-} p \bar{n}$ requires the detection of an antineutron. This is accomplished by identifying annihilation showers in the CsI calorimeter. Antiprotons and antineutrons annihilate with nucleons in the calorimeter. These annihilations result in showers with
different characteristics than those from photons or charged particles. We use antiproton annihilation showers to define the antineutron selection criteria since we are unable to isolate a sample of antineutrons in data. Our antiproton sample consists of $1.6 \times 10^5 \bar{p}$'s from reconstructed $\bar{\Lambda} \rightarrow \bar{p}\pi^+$ decays, in which the daughter antiprotons are selected by dE/dx and TOF response. The isolation of this sample is independent of calorimeter response and therefore allows us to evaluate our shower-based selection criteria. We can expect these same criteria to be similarly effective for antineutrons.

We find that antinucleons typically deposit a substantial amount of energy in a laterally broad shower, which has energy $E_{\text{main}}$, and a lesser amount of energy in adjacent satellite showers, whose energy is added to $E_{\text{main}}$ to define $E_{\text{group}}$. The selection of showers with $E_{\text{main}} > 500$ MeV and $E_{\text{group}} > 800$ MeV is useful in suppressing backgrounds, while retaining many antinucleon annihilation showers. The main shower must have polar angle $\theta$ with respect to the incoming positron direction of $45^\circ < \theta < 135^\circ$ to ensure that it is located in that part of the calorimeter that has the best resolution, must have a lateral shape broader than typical photons, and must not match the projection of any charged track trajectory. Baryon number conservation serves as an added background suppressant: once we require that there be a proton, the likelihood of an annihilation-like shower in the event to be an antineutron increases significantly. The reconstruction efficiency as a function of momentum for antineutrons in a Monte Carlo sample of $B^0 \rightarrow D^{*-} p \bar{n}$ events in which the $B^0$ selection criteria have been applied is shown in Figure 3.

![Figure 3](image.png)

**FIG. 3.** Antineutron reconstruction efficiency derived from simulated $B^0 \rightarrow D^{*-} p \bar{n}$ events.

The measured shower energy for an antineutron, $E_{\text{group}}$, does not give an accurate measurement of the total energy of the antineutron. We therefore assign the energy of the antineutron candidate using $E(\bar{n}) = E_{\text{beam}} - E(D^{*-}) - E(p)$. We then use this energy, together with the position of the antineutron shower, to calculate the momentum of the antineutron candidate. This momentum is added to the momenta of the $D^{*-}$ and $p$ candidates to give the momentum of the $B^0$ meson, $p(B)$. The $B^0$ candidate mass is then calculated with $M(B) = \sqrt{E_{\text{beam}}^2 - p(B)^2}$.

The mass resolution of the reconstructed $B^0$ meson is estimated from a Monte Carlo simulation to be Gaussian with a width $\sigma = 3.1$ MeV, demonstrating that the lack of a direct measurement of the antineutron energy does not seriously degrade the $M(B)$ resolution relative to $B^0 \rightarrow D^{*-} p \bar{p} \pi^+$. However, for this mode we cannot use the requirement that
\( \Delta E \) is consistent with zero, as we do not have two independent measures of the energy of the \( B^0 \).

In reconstructing \( B^0 \to D^{*-} p \bar{n} \) we could also be reconstructing \( B^0 \to D^{*-} D^+_s \) with \( D^+_s \to p \bar{n} \). This latter decay has not been observed but could occur via \( c \bar{s} \) annihilation. We might also be including events that are \( B^0 \to D^{*-} D^+_s \) with \( D^+_s \to D^{**+} \) or \( D^{**+} \to D^{*+} \pi^0 \) and \( D^+_s \to p \bar{n} \). These events will populate the \( M(B) \) signal region but with a broader signal peak due to the missing soft photon or \( \pi^0 \). We eliminate these two types of decay by rejecting events with \( 1.91 < M(p\bar{n}) \) (GeV) < 2.04 GeV, for a loss of only 9% in the relative reconstruction efficiency.

The final data \( M(B) \) distribution, shown in Fig. 2(b), is fit with a Monte Carlo predicted Gaussian width of \( \sigma = 3.1 \) MeV and gives a signal yield of 24.0\(^{+5.6}_{-5.0} \) events. If \( \sigma \) is allowed to float, a value of 2.6 \( \pm 0.4 \) MeV is found, consistent with the Monte Carlo expectation.

We use a Monte Carlo simulation to calculate detection efficiencies to be 0.52% for \( B^0 \to D^{*-} p \bar{p} \pi^+ \), and 0.34% for \( B^0 \to D^{*-} p \bar{n} \), where these numbers include all the relevant branching fractions of the daughters. The Monte Carlo generation of the decays assume no resonant sub-structure. No evidence of sub-structure has been found in the signal candidates. However, we will allow for possibility of sub-structure, which would alter the efficiency, in our estimation of the systematic uncertainties.

Whereas the Monte Carlo simulation has been well tested for charged particles and photons, this is the first measurement that has explicitly needed the efficiency for antinucleon annihilations in the calorimeter. We find a discrepancy for antiproton annihilation showers between the Monte Carlo and data. The reconstruction efficiency for Monte Carlo and data for antiprotons, as determined from the aforementioned \( \Lambda \) sample, is shown in Fig. 3(a). We find that the antiproton reconstruction efficiency is overestimated by the GEANT simulation prediction. We assume that the Monte Carlo simulation for the antineutron efficiency is similarly overestimated and therefore must be corrected. Weighting the efficiency correction for antiprotons by the expected antineutron momentum spectrum results in an antineutron selection efficiency which is 21% lower than the GEANT Monte Carlo simulation. In Fig. 3(b) we show the antineutron momentum spectrum generated in Monte Carlo for \( B \to D^{*-}p\bar{n} \) decays.

We search for, but do not find, resonant substructure contributions to \( B^0 \to D^{*-}p\bar{p}\pi^+ \) and \( B^0 \to D^{*-}p\bar{n} \) decays. Examples of possible substructure arise from a heavy charmed baryon decaying strongly to \( (p D^{*-}) \) for \( B^0 \to D^{*-} p \bar{p} \pi^+ \) and \( (\bar{n} D^{*-}) \) for \( B^0 \to D^{*-} p \bar{n} \), and a resonance of the virtual \( W \) decaying to \( p\bar{p}\pi^+ \). We also study the effect on the Monte Carlo reconstruction efficiency of a two-body decay into \( D^{*-}X \), and find no evidence from the kinematic distribution of the daughter particles for decays of this type. We also find insignificant background from \( B \) decays with a charmed baryon final state or from other \( B \to D^{*-}X \) modes.

We have considered many sources of systematic uncertainty of these branching fraction measurements. Systematic uncertainties shared by both modes are statistical uncertainty of \( D^0 \) branching fractions (0.6%) and \( D^{*-} \) branching fraction (1.4%), \( D^{*-} \) reconstruction due to kinematic fitting and particle identification (5.0%), and Monte Carlo statistics (5.0%). Systematic uncertainties which differ for the two modes, and which we quote in parenthesis for \( B^0 \to D^{*-} p \bar{p} \pi^+ \) and \( B^0 \to D^{*-} p \bar{n} \), respectively, are: tracking, 1% per track (6.6%, 4.6%), proton identification criteria (8%, 4%), and n-body versus two-body for decay kinematic fitting and particle identification (5.0%), and Monte Carlo statistics (5.0%).
FIG. 4. (a) Antiproton reconstruction efficiency. Squares represent Monte Carlo efficiency and triangles that of the data. (b) Monte Carlo antineutron momentum spectrum in simulated $B^0 \to D^{*-} p \bar{n}$ decays.

matics (5%, 3%). No statistically significant $\Delta$ baryon contribution to the $D^{*-} p \bar{p} \pi^+$ yield was found. We place a systematic uncertainty due to a possible $\Delta$ baryon contribution to the $B^0 \to D^{*-} p \bar{p} \pi^+$ signal. Also, we assign a 5% uncertainty on the yield of $B^0 \to D^{*-} p \bar{n}$ due to the possibility of $\Delta$ baryons with a missing $\pi$ distorting the background shape in this mode. The systematic uncertainty for antineutron identification is estimated to be 15%. The quadrature sum of all systematic uncertainties is 15% for $B^0 \to D^{*-} p \bar{p} \pi^+$, and 19% for $B^0 \to D^{*-} p \bar{n}$.

In conclusion, we have made the first observation of decay modes of the $B^0$ of the type $B \to DN\bar{N}X$, which may contribute substantially to the total observed $B \to Baryons$ rate. We measure the branching fractions $B(B^0 \to D^{*-} p \bar{p} \pi^+) = (6.5^{+1.3}_{-1.2} \pm 1.0) \times 10^{-4}$, and $B(B^0 \to D^{*-} p \bar{n}) = (14.5^{+3.4}_{-3.0} \pm 2.7) \times 10^{-4}$.

We gratefully acknowledge the effort of the CESR staff in providing us with excellent luminosity and running conditions.
