ABSTRACT

Given multiple source datasets with labels, how can we train a target model with no labeled data? Multi-source domain adaptation (MSDA) aims to train a model using multiple source datasets different from a target dataset in the absence of target data labels. MSDA is a crucial problem applicable to many practical cases where labels for the target data are unavailable due to privacy issues. Existing MSDA frameworks are limited since they align data without considering conditional distributions \( p(x|y) \) of each domain. They also miss a lot of target label information by not considering the target label at all and relying on only one feature extractor. In this paper, we propose Ensemble Multi-source Domain Adaptation with Pseudolabels (ENMDAP), a novel method for multi-source domain adaptation. ENMDAP exploits label-wise moment matching to align conditional distributions \( p(x|y) \), using pseudolabels for the unavailable target labels, and introduces ensemble learning theme by using multiple feature extractors for accurate domain adaptation. Extensive experiments show that ENMDAP provides the state-of-the-art performance for multi-source domain adaptation tasks in both of image domains and text domains.

1 INTRODUCTION

Given multiple source datasets with labels, how can we train a target model with no labeled data? A large training data are essential for training deep neural networks. Collecting abundant data is unfortunately an obstacle in practice; even if enough data are obtained, manually labeling those data is prohibitively expensive. Using other available or much cheaper datasets would be a solution for these limitations; however, indiscriminate usage of other datasets often brings severe generalization error due to the presence of dataset shifts (Torralba & Efros (2011)). Unsupervised domain adaptation (UDA) tackles these problems where no labeled data from the target domain are available, but labeled data from other source domains are provided. Finding out domain-invariant features has been the focus of UDA since it allows knowledge transfer from the labeled source dataset to the unlabeled target dataset. There have been many efforts to transfer knowledge from a single source domain to a target one. Most recent frameworks minimize the distance between two domains by deep neural networks and distance-based techniques such as discrepancy regularizers (Long et al. (2015; 2016; 2017)), adversarial networks (Ganin et al. (2016; Tzeng et al. (2017)), and generative networks (Liu et al. (2017; Zhu et al. (2017); Hoffman et al. (2018b)).

While the above-mentioned approaches consider one single source, we address multi-source domain adaptation (MSDA), which is very crucial and more practical in real-world applications as well as more challenging. MSDA is able to bring significant performance enhancement by virtue of accessibility to multiple datasets as long as multiple domain shift problems are resolved. Previous works have extensively presented both theoretical analysis (Ben-David et al. (2010); Mansour et al. (2008; Crammer et al. (2008); Hoffman et al. (2018a; Zhao et al. (2018; Zellinger et al. (2020)) and models (Zhao et al. (2018; Xu et al. (2018; Peng et al. (2019)) for MSDA. MDAN (Zhao et al. (2018) and DCTN (Xu et al. (2018)) build adversarial networks for each source domain to generate features domain-invariant enough to confound domain classifiers. However, these approaches do not encompass the shifts among source domains, counting only shifts between source and target domain. M3SDA (Peng et al. (2019) adopts moment matching strategy but makes the unrealistic

∗ Corresponding author
assumption that matching the marginal probability $p(x)$ would guarantee the alignment of the conditional probability $p(x|y)$. Most of these methods also do not fully exploit the knowledge of target domain, imputing to the inaccessibility to the labels. Furthermore, all these methods leverage one single feature extractor, which possibly misses important information regarding label classification.

In this paper, we propose ENMDAP, a novel MSDA framework which mitigates the limitations of these methods of not explicitly considering conditional probability $p(x|y)$, and relying on only one feature extractor. The model architecture is illustrated in Figure 1. ENMDAP aligns the conditional probability $p(x|y)$ by utilizing label-wise moment matching. We employ pseudolabels for the inaccessible target labels to maximize the usage of the target data. Moreover, integrating the features from multiple feature extractors gives abundant information about labels to the extracted features. Extensive experiments show the superiority of our proposed methods.

Our contributions are summarized as follows:

- **Method.** We propose ENMDAP, a novel approach for MSDA that effectively obtains domain-invariant features from multiple domains by matching conditional probability $p(x|y)$, not marginal one, utilizing pseudolabels for inaccessible target labels to fully deploy target data, and using multiple feature extractors. It allows domain-invariant features to be extracted, capturing the intrinsic differences of different labels.
- **Analysis.** We theoretically prove that minimizing the label-wise moment matching loss is relevant to bounding the target error.
- **Experiments.** We conduct extensive experiments on image and text datasets. We show that 1) ENMDAP provides the state-of-the-art accuracy, and 2) each of our main ideas significantly contributes to the superior performance.

2 RELATED WORK

**Single-source Domain Adaptation.** Given a labeled source dataset and an unlabeled target dataset, single-source domain adaptation aims to train a model that performs well on the target domain. The challenge of single-source domain adaptation is to reduce the discrepancy between the two domains and to obtain appropriate domain-invariant features. Various discrepancy measures such as Maximum Mean Discrepancy (MMD) (Tzeng et al. (2014); Long et al. (2015; 2016; 2017); Ghifary et al. (2016)) and KL divergence (Zhuang et al. (2015)) have been used as regularizers. Inspired from the insight that the domain-invariant features should exclude the clues about its domain, constructing adversarial networks against domain classifiers has shown superior performance. Liu et al. (2017) and Hoffman et al. (2018b) deploy GAN to transform data across the source and target domain, while Ganin et al. (2016) and Tzeng et al. (2017) leverage the adversarial networks to extract common features of the two domains. Unlike these works, we focus on multiple source domains.

**Multi-source Domain Adaptation.** Single-source domain adaptation should not be naively employed for multiple source domains due to the shifts between source domains. Many previous works have tackled MSDA problems theoretically. Mansour et al. (2008) establish distribution weighted combining rule that the weighted combination of source hypotheses is a good approximation for the target hypothesis. The rule is further extended to a stochastic case with joint distribution over the input and the output space in Hoffman et al. (2018a). Crammer et al. (2008) propose the general theory of how to sift appropriate samples out of multi-source data using expected loss. Efforts to find out transferable knowledge from multiple sources from the causal viewpoint are made in Zhang et al. (2015). There have been salient studies on the learning bounds for MSDA. Ben-David et al. (2010) found the generalization bounds based on $\mathcal{H}(\Delta \mathcal{H})$-divergence, which are further tightened by Zhao et al. (2018). Frameworks for MSDA have been presented as well. Zhao et al. (2018) propose learning algorithms based on the generalization bounds for MSDA. DCTN (Xu et al. (2018)) resolves domain and category shifts between source and target domains via adversarial networks. M³SDA (Peng et al. (2019)) associates all the domains into a common distribution by aligning the moments of the feature distributions of multiple domains. However, all these methods do not consider multi-mode structures (Pei et al. (2018)) that differently labeled data follow distinct distributions, even if they are drawn from the same domain. Also, the domain-invariant features in these methods contain the label information for only one label classifier which lead these methods to miss a large amount of label information. Different from these methods, our frameworks fully count the multimodal structures handling the data distributions in a label-wise manner and minimize the label information loss considering multiple label classifiers.
Figure 1: ENMDAP for \( n=2 \). ENMDAP consists of \( n \) pairs of feature extractor and label classifier, one extractor classifier, and one final label classifier. Colors and symbols of the markers indicate domains and class labels of the data, respectively.

**Moment Matching.** Domain adaptation has deployed the moment matching strategy to minimize the discrepancy between source and target domains. MMD regularizer (Tzeng et al. (2014); Long et al. (2015, 2016, 2017); Chitany et al. (2016)) can be interpreted as the first-order moment while Sun et al. (2016) address second-order moments of source and target distributions. Zellinger et al. (2017) investigate the effect of higher-order moment matching. M\(^3\)SDA (Peng et al. (2019)) demonstrates that moment matching yields remarkable performance also with multiple sources. While previous works have focused on matching the moments of marginal distributions for single-source adaptation, we handle conditional distributions in multi-source scenarios.

3 **Proposed Method**

In this section, we describe our proposed method, ENMDAP. We first formulate the problem definition in Section 3.1. Then, we describe our main ideas in Section 3.2. Section 3.3 elaborates how to match label-wise moment with pseudolabels and Section 3.4 extends the concept of ensemble learning. Figure 1 shows the overview of ENMDAP.

3.1 **Problem Definition**

Given a set of labeled datasets from \( N \) source domains \( S_1, \ldots, S_N \) and an unlabeled dataset from a target domain \( T \), we aim to construct a model that minimizes test error on \( T \). We formulate source domain \( S_i \) as a tuple of the data distribution \( \mu_{S_i} \) on data space \( X \) and the labeling function \( l_{S_i} : S_i = (\mu_{S_i}, l_{S_i}) \). Source dataset drawn with the distribution \( \mu_{S_i} \) is denoted as \( X_{S_i} = \{ (x_{S_i}^j, y_{S_i}^j) \}^{n_{S_i}}_{j=1} \). Likewise, the target domain and the target dataset are denoted as \( T = (\mu_T, l_T) \) and \( X_T = \{ x_T^j \}^{n_T}_{j=1} \), respectively. We narrow our focus down to homogeneous settings in classification tasks: all domains share the same data space \( X \) and label set \( C \).

3.2 **Overview**

We propose ENMDAP based on the following observations: 1) existing methods focus on aligning the marginal distributions \( p(x) \) not the conditional ones \( p(x|y) \), 2) knowledge of the target data is not fully employed as no target label is given, and 3) there exists a large amount of label information loss since domain-invariant features are extracted for only one single label classifier. Thus, we design ENMDAP aiming to solve the limitations. Designing such method entails the following challenges:

1. **Matching conditional distributions.** How can we align the conditional distribution, \( p(x|y) \), of multiple domains not the marginal one, \( p(x) \)?
2. **Exploitation of the target data.** How can we fully exploit the knowledge of the target data despite the absence of the target labels?
We describe how E

We propose the following main ideas to address the challenges:

1. **Label-wise moment matching (Section 3.3).** We match the label-wise moments of the domain-invariant features so that the features with the same labels have similar distributions regardless of their original domains.

2. **Pseudolabels (Section 3.3).** We use pseudolabels as alternatives to the target labels.

3. **Ensemble of feature representations (Section 3.4).** We learn to extract ensemble of features from multiple feature extractors, each of which involves distinct domain-invariant features for its own label classifier.

### 3.3 Label-wise Moment Matching with Pseudolabels

We describe how ENMDAP matches conditional distributions $p(x|y)$ of the features from multiple distinct domains. In ENMDAP, a feature extractor $f_e$ and a label classifier $f_{lc}$ lead the features to be domain-invariant and label-informative at the same time. The feature extractor $f_e$ extracts features from data, and the label classifier $f_{lc}$ receives the features and predicts the labels for the data. We train the two components, $f_e$ and $f_{lc}$, according to the losses for label-wise moment matching and label classification, which make the features domain-invariant and label-informative, respectively.

**Label-wise Moment Matching.** To achieve the alignment of domain-invariant features, we define a label-wise moment matching loss as follows:

$$
\mathcal{L}_{imm,K} = \frac{1}{|C|} \left( \binom{N + 1}{2} \right)^{-1} \sum_{k=1}^{K} \sum_{c \in C} \sum_{j \in D^c} \left\| \frac{1}{n_{D,c}} \sum_{j:y_j^c = c} f_e(x_j^{D^c})^k - \frac{1}{n_{D',c}} \sum_{j:y_j^c = c} f_e(x_j^{D'})^k \right\|_2^2 ,
$$

where $K$ is a hyperparameter indicating the maximum order of moments considered by the loss, $D$ and $D'$ are two distinct domains amongst the $N + 1$ domains, and $n_{D,c}$ is the number of data labeled as $c$ in $X_D$. We introduce pseudolabels for the target data, which are determined by the outputs of the model currently being trained, to manage the absence of the ground truths for the target data. In other words, we leverage $f_{lc}(f_e(x^T))$ to give the pseudolabel to the target data $x^T$. Drawing the pseudolabels using the incomplete model, however, brings mis-labeling issue which impedes further training. To alleviate this problem, we set a threshold $\tau$ and assign the pseudolabels to the target data only when the prediction confidence is greater than the threshold. The target examples with low confidence are not pseudolabeled and not counted in label-wise moment matching.

By minimizing $\mathcal{L}_{imm,K}$, the feature extractor $f_e$ aligns data from multiple domains by bringing consistency in distributions of the features with the same labels. The data with distinct labels are aligned independently, taking account of the multimode structures that differently labeled data follow different distributions.

**Label Classification.** The label classifier $f_{lc}$ gets the features projected by $f_e$ as inputs and makes the label predictions. The label classification loss is defined as follows:

$$
\mathcal{L}_{lc} = \frac{1}{N} \sum_{i=1}^{N} \frac{1}{n_i^{S_i}} \sum_{j=1}^{n_i^{S_i}} \mathcal{L}_{ce}(f_{lc}(f_e(x_j^{S_i})), y_j^{S_i}) ,
$$

where $\mathcal{L}_{ce}$ is the softmax cross-entropy loss. Minimizing $\mathcal{L}_{lc}$ separates the features with different labels so that each of them gets label-distinguishable.

### 3.4 Ensemble of Feature Representations

In this section, we introduce ensemble learning for further enhancement. Features extracted with the strategies elaborated in the previous section contain the label information for a single label classifier. However, each label classifier leverages only limited label characteristics, and thus the conventional scheme to adopt only one pair of feature extractor and label classifier captures only a small part of the label information. Our idea is to leverage an ensemble of multiple pairs of feature extractor and label classifier in order to make the features to be more label-informative.

We train multiple pairs of feature extractor and label classifier in parallel following the label-wise moment matching approach explained in Section 3.3. Let $n$ denote the number of the feature extractors in the overall model. We denote the $n$ (feature extractor, la-
bel classifier) pairs as \((f_{e1}, f_{lc1}), (f_{e2}, f_{lc2}), \ldots, (f_{en}, f_{lcn})\) and the \(n\) resultant features as feat\(_1\), feat\(_2\), \ldots, feat\(_n\) where feat\(_i\) is the output of the feature extractor \(f_{ei}\). After obtaining \(n\) different feature mapping modules, we concatenate the \(n\) features into one vector \(feat_{final} = concat(feat_1, feat_2, \ldots, feat_n)\). The final label classifier \(f_{lc,final}\) takes the concatenated feature as input, and predicts the label of the feature.

Naively exploiting multiple feature extractors, however, does not guarantee the diversity of the features, since it resorts to the randomness. Thus, we introduce a new model component, extractor classifier, which separates the features from different extractors. The extractor classifier \(f_{ec}\) gets the features generated by a feature extractor as inputs and predicts which feature extractor has generated the features. For example, if \(n = 2\), the extractor classifier \(f_{ec}\) attempts to predict whether the input feature is extracted by the extractor \(f_{e1}\) or \(f_{e2}\). By training the extractor classifier and multiple feature extractors at once, we explicitly diversify the features obtained from different extractors. We train the extractor classifier utilizing the feature diversifying loss, \(L_{fd}\):

\[
L_{fd} = \frac{1}{N+1} \left( \sum_{i=1}^{N} \frac{1}{n_S} \sum_{j=1}^{n} \sum_{k=1}^{n_T} L_{ce}(f_{ec,k}(x_j^S), k) + \frac{1}{n_T} \sum_{j=1}^{n_T} \sum_{k=1}^{n_T} L_{ce}(f_{ec,k}(x_j^T), k) \right),
\]

(3)

where \(n\) is the number of feature extractors.

### 3.5 ENMDAP: Ensemble Multi-Source Domain Adaptation with Pseudolabels

Our final model ENMDAP consists of \(n\) pairs of feature extractor and label classifier, \((f_{e1}, f_{lc1}), (f_{e2}, f_{lc2}), \ldots, (f_{en}, f_{lcn})\), one extractor classifier \(f_{ec}\), and one final label classifier \(f_{lc,final}\). We first train the entire model except the final label classifier with the loss \(L\):

\[
L = \sum_{k=1}^{n} L_{lc,k} + \alpha \sum_{k=1}^{n} L_{lmm,K,k} + \beta L_{fd},
\]

(4)

where \(L_{lc,k}\) is the label classification loss of the classifier \(f_{lc,k}\), \(L_{lmm,K,k}\) is the label-wise moment matching loss of the feature extractor \(f_{e,k}\), and \(\alpha\) and \(\beta\) are the hyperparameters. Then, the final label classifier is trained with respect to the label classification loss \(L_{lc,final}\) using the concatenated features from multiple feature extractors.

### 4 Analysis

We present a theoretical insight regarding the validity of the label-wise moment matching loss. For simplicity, we tackle only binary classification tasks. The error rate of a hypothesis \(h\) on a domain \(D\) is denoted as \(\epsilon_D(h) = Pr\{h(x) \neq l_D(x)\}\) where \(l_D\) is the labeling function on the domain \(D\). We first introduce \(k\)-th order label-wise moment divergence.

**Definition 1.** Let \(D\) and \(D'\) be two domains over an input space \(X \subset \mathbb{R}^n\) where \(n\) is the dimension of the inputs. Let \(C\) be the set of the labels, and \(\mu(x)\) and \(\mu'(x)\) be the data distribution given that the label is \(c\), i.e., \(\mu_c(x) = \mu(x|y = c)\) and \(\mu'_c(x) = \mu'(x|y = c)\) for the data distribution \(\mu\) and \(\mu'\) on the domains \(D\) and \(D'\), respectively. Then, the \(k\)-th order label-wise moment divergence \(d_{LM,k}(D, D')\) of the two domains \(D\) and \(D'\) over \(X\) is defined as

\[
d_{LM,k}(D, D') = \sum_{c \in C} \sum_{i \in \Delta_k} \Big| p(c) \int \mu_c(x) \prod_{j=1}^{n} (x_j)^{i_j} dx - p'(c) \int \mu'_c(x) \prod_{j=1}^{n} (x_j)^{i_j} dx \Big|,
\]

(5)

where \(\Delta_k = \{i = (i_1, \ldots, i_n) \in \mathbb{N}^n | \sum_{j=1}^{n} i_j = k\}\) is the set of the tuples of the nonnegative integers, which add up to \(k\), \(p(c)\) and \(p'(c)\) are the probability that arbitrary data from \(D\) and \(D'\) to be labeled as \(c\) respectively, and the data \(x \in X\) is expressed as \((x_1, \ldots, x_n)\).

The ultimate goal of MSDA is to find a hypothesis \(h\) with the minimum target error. We nevertheless train the model with respect to the source data since ground truths for the target are unavailable. Let \(N\) datasets be drawn from \(N\) labeled source domains \(S_1, \ldots, S_N\) respectively. We denote \(i\)-th source dataset \(X_{S_i}\) as \(\{(x_{j}^{S_i}, y_{j}^{S_i})\}_{j=1}^{n_{S_i}}\). The empirical error of hypothesis \(h\) in \(i\)-th source domain \(S_i\) estimated with \(X_{S_i}\) is formulated as \(\hat{\epsilon}_{S_i}(h) = \frac{1}{n_{S_i}} \sum_{j=1}^{n_{S_i}} 1_{h(x_j^{S_i}) \neq y_j^{S_i}}\). Given a weight vector \(\alpha = (\alpha_1, \alpha_2, \ldots, \alpha_N)\) such that \(\sum_{i=1}^{N} \alpha_i = 1\), the weighted empirical source error is formulated as \(\hat{\epsilon}_\alpha(h) = \sum_{i=1}^{N} \alpha_i \hat{\epsilon}_{S_i}(h)\). We extend the theorems in [Ben-David et al. (2010); Peng et al. (2019)]
and derive a bound for the target error $\epsilon_T(h)$, for $h$ trained with source data, in terms of $k$-th order label-wise moment divergence.

**Theorem 1.** Let $\mathcal{H}$ be a hypothesis space of VC dimension $d$, $n_{S_i}$ be the number of samples from source domain $S_i$, $m = \sum_{i=1}^{N} n_{S_i}$ be the total number of samples from $N$ source domains $S_1, \ldots, S_N$, and $\beta = (\beta_1, \ldots, \beta_N)$ with $\beta_i = \frac{n_{S_i}}{m}$. Let us define a hypothesis $h = \arg\min_{h \in \mathcal{H}} \epsilon_{\alpha}(h)$ that minimizes the weighted empirical source error, and a hypothesis $h^* = \arg\min_{h \in \mathcal{H}} \epsilon_T(h)$ that minimizes the true target error. Then, for any $\delta \in (0, 1)$ and $\epsilon > 0$, there exist $N$ integers $n_{1}^{\epsilon}, \ldots, n_{N}^{\epsilon}$ and $N$ constants $a_{n_1}, \ldots, a_{n_N}$ such that

$$
\epsilon_T(\hat{h}) \leq \epsilon_T(h^*_T) + \eta_{\alpha, \beta, m, \delta} + \epsilon + \sum_{i=1}^{N} \lambda_i \left(2\lambda_i + a_{n_i} \sum_{k=1}^{n_i} d_{L,M,k}(S_i, T)\right)
$$

with probability at least $1 - \delta$, where $\eta_{\alpha, \beta, m, \delta} = 4 \sqrt{\left(\sum_{i=1}^{N} \frac{n_{i}^{2}}{m}\right) \left(2d(\log(\frac{2m}{\delta\alpha})+1)+2\log(\frac{1}{\delta})\right)}$ and $\lambda_i = \min_{h \in \mathcal{H}} \{\epsilon_T(h) + \epsilon_{S_i}(h)\}$.

**Proof.** See the appendix.

Speculating that all datasets are balanced against the annotations, i.e., $p(c) = p'(c) = \frac{1}{C}$, for any $c \in C$, $L_{lm,m,K}$ is expressed as the sum of the estimates of $d_{L,M,k}$ with $k = 1, \ldots, K$. The theorem provides an insight that label-wise moment matching allows the model trained with source data to have performance comparable to the optimal one on the target domain.

5 EXPERIMENTS

We conduct experiments to answer the following questions of ENMDAP.

**Q1** Accuracy (Section 5.2). How well does ENMDAP perform in classification tasks?

**Q2** Ablation Study (Section 5.3). How much does each component of ENMDAP contribute to performance improvement?

**Q3** Effects of Degree of Ensemble (Section 5.4). How does the performance change as the number $n$ of the pairs of the feature extractor and the label classifier increases?

5.1 EXPERIMENTAL SETTINGS

**Datasets.** We use three kinds of datasets, Digits-Five, Office-Caltech10, and Amazon Reviews. Digits-Five consists of five datasets for digit recognition: MNIST (LeCun et al. (1998)), MNIST-$M^*$ (Ganin & Lempitsky (2015)), SVHN (Netzer et al. (2011)), SynthDigits (Ganin & Lempitsky (2015)), and USPS (Hastie et al. (2001)). We set one of them as a target domain and the rest as source domains. Following the conventions in prior works (Xu et al. (2018); Peng et al. (2019)), we randomly sample 25000 instances from the source training set and 9000 instances from the target training set to train the model except for USPS for which the whole training set is used. Amazon Reviews is the dataset for image classification with 10 categories that Office31 dataset and Caltech dataset have in common. It involves four different domains: Amazon, Caltech, DSLR, and Webcam. We double the number of data by data augmentation and exploit all the original data and augmented data as training data and test data respectively.Amazon Reviews dataset contains customers’ reviews on 4 product categories: Books, DVDs, Electronics, and Kitchen appliances. The instances are encoded into 5000-dimensional vectors and are labeled as being either positive or negative depending on their sentiments. We set each of the four categories as a target and the rest as sources. For all the domains, 2000 instances are sampled for training, and the rest of the data are used for the test. Details about the datasets are summarized in appendix.

Competitors. We use 3 MSDA algorithms, DCTN (Xu et al. (2018)), M²SDA (Peng et al. (2019)), and M²SDA-β (Peng et al. (2019)), with state-of-the-art performances as baselines. All the frameworks share the same architecture for the feature extractor, the domain classifier, and the label classifier for consistency. For Digits-Five, we use convolutional neural networks based on LeNet5 (LeCun et al. (1998)). For Office-Caltech10, ResNet50 (He et al. (2016)) pretrained on ImageNet is used as the backbone architecture. For Amazon Reviews, the feature extractor is composed of three fully-connected layers each with 1000, 500, and 100 output units, and a single fully-connected layer with 100 input units and 2 output units is adopted for both of the extractor and label classifiers. With Digits-Five, LeNet5 (LeCun et al. (1998)) and ResNet14 (He et al. (2016)) without any adaptation are additionally investigated in two different manners: Source Combined and Single Best. In Source Combined, multiple source datasets are simply combined and fed into a model. In Single Best, we train the model with each source dataset independently, and report the result of the best performing one. Likewise, ResNet50 and MLP consisting of 4 fully-connected layers with 1000, 500, 100, and 2 units are investigated without adaptation for Office-Caltech10 and Amazon Reviews respectively.

Training Details. We train our models for Digits-Five with Adam optimizer (Kingma & Ba (2015)) with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and the learning rate of 0.0004 for 100 epochs. All images are scaled to 32 × 32 and the mini batch size is set to 128. We set the hyperparameters $\alpha = 0.0005$, $\beta = 1$, and $K = 2$. For the experiments with Office-Caltech10, all the modules comprising our model are trained following SGD with the learning rate 0.001, except that the optimizers for feature extractors have the learning rate 0.0001. We scale all the images to 224 × 224 and set the mini batch size to 48. All the hyperparameters are kept the same as in the experiments with Digits-Five. For Amazon Reviews, we train the models for 50 epochs using Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.999$, and the learning rate of 0.0001. We set $\alpha = \beta = 1$, $K = 2$, and the mini batch size to 100. For every experiment, the confidence threshold $\tau$ is set to 0.9.
of label information. Even regression, which may require modification in the pseudolabeling method.

Future works include extending our approach to other tasks such as matching and adding ensemble learning. The results are summarized in Table 2. Note that EMDAP provides the best accuracy in all the datasets, showing their consistent superiority in both image datasets (Digits-Five, Office-Caltech10) and text dataset (Amazon Reviews). The enhancement is especially remarkable when MNIST-M is the target domain in Digits-Five, improving the accuracy by 11.48% compared to the state-of-the-art methods.

5.2 Performance Evaluation

We evaluate the performance of EMDAP with $n = 2$ against the competitors. We repeat experiments for each setting five times and report the mean and the standard deviation. The results are summarized in Tables [1]. Note that EMDAP provides the best accuracy in all the datasets, showing their consistent superiority in both image datasets (Digits-Five, Office-Caltech10) and text dataset (Amazon Reviews). The enhancement is especially remarkable when MNIST-M is the target domain in Digits-Five, improving the accuracy by 11.48% compared to the state-of-the-art methods.

5.3 Ablation Study

We perform an ablation study on Digits-Five to identify what exactly enhances the performance of EMDAP. We compare EMDAP with 3 of its variants: MDAP-L, MDAP, and EMDAP-R. MDAP-L has the same strategies as M3DA, aligning moments regardless of the labels of the data. MDAP trains the model without ensemble learning theme. EMDAP-R exploits ensemble learning strategy but relies on randomness without extractor classifier and feature diversifying loss.

The results are shown in Table [2]. By comparing MDAP-L and MDAP, we observe that considering labels in moment matching plays a significant role in extracting domain-invariant features. The remarkable performance gap between MDAP and EMDAP with $n = 2$ verifies the effectiveness of ensemble learning. On the other hand, the performance of EMDAP-R and EMDAP have little difference. It indicates that two feature extractors trained independently without any diversifying techniques are unlikely to be correlated even though it resorts to randomness.

5.4 Effects of Ensemble

We vary $n$, the number of pairs of feature extractor and label classifier, and repeat the performance evaluation on Digits-Five. The results are summarized in Table [2]. While ensemble of two pairs gives much better performance than the model with one single pair, using more than two pairs rarely brings further improvement. This result demonstrates that two pairs of feature extractor and label classifier are able to cover most information without losing important label information in Digits-Five. It is notable that increasing $n$ sometimes brings small performance degradation. As more feature extractors are adopted to obtain final features, the complexity of final features increases. It is harder for the final label classifiers to manage the features with high complexity compared to the simple ones. This deteriorates the performance when we exploit more than two feature extractors.

6 Conclusion

We propose EMDAP, a novel framework for the multi-source domain adaptation problem. EMDAP overcomes the problems in the existing methods of not directly addressing conditional distributions of data $p(x|y)$, not fully exploiting knowledge of target data, and missing large amount of label information. EMDAP aligns data from multiple source domains and the target domain considering the data labels, and exploits pseudolabels for unlabeled target data. EMDAP further enhances the performance by introducing multiple feature extractors. Our framework exhibits superior performance on both image and text classification tasks. Considering labels in moment matching and adding ensemble learning theme is shown to bring remarkable performance enhancement through ablation study. Future works include extending our approach to other tasks such as regression, which may require modification in the pseudolabeling method.

A.1 Proof for Theorem 1

We prove Theorem 1 in the paper by extending the proof in the existing studies [Ben-David et al. (2010); Peng et al. (2019)]. We first define k-th order label-wise moment divergence $d_{LM,k}$, and disagreement ratio $\epsilon(D(h_1, h_2)$ of the two hypotheses $h_1, h_2 \in \mathcal{H}$ on the domain $D$.

**Definition 1.** Let $D$ and $D'$ be two domains over an input space $\mathcal{X} \subset \mathbb{R}^n$ where $n$ is the dimension of the inputs. Let $C$ be the set of the labels, and $\mu_c(x)$ and $\mu'_c(x)$ be the data distributions given that the label is $c$, i.e., $\mu_c(x) = \mu(x|y = c)$ and $\mu'_c(x) = \mu'(x|y = c)$ for the data distribution $\mu$ and $\mu'$ on the domains $D$ and $D'$, respectively. Then, the $k$-th order label-wise moment divergence $d_{LM,k}(D, D')$ of the two domains $D$ and $D'$ over $\mathcal{X}$ is defined as

$$d_{LM,k}(D, D') = \sum_{c \in C} \sum_{i \in \Delta_k} |p(c) \int_{\mathcal{X}} \mu_c(x) \prod_{j=1}^{n} (x_j)^{i_j} dx - p'(c) \int_{\mathcal{X}} \mu'_c(x) \prod_{j=1}^{n} (x_j)^{i_j} dx|,$$

where $\Delta_k = \{i = (i_1, \ldots, i_n) \in \mathbb{N}_0^n | \sum_{j=1}^{n} i_j = k\}$ is the set of the tuples of the nonnegative integers, which add up to $k$, $p(c)$ and $p'(c)$ are the probability that arbitrary data from $D$ and $D'$ to be labeled as $c$ respectively, and the data $x \in \mathcal{X}$ is expressed as $(x_1, \ldots, x_n)$.

**Definition 2.** Let $D$ be a domain over an input space $\mathcal{X} \subset \mathbb{R}^n$ with the data distribution $\mu(x)$. Then, we define the disagreement ratio $\epsilon(D(h_1, h_2)$ of the two hypotheses $h_1, h_2 \in \mathcal{H}$ on the domain $D$ as

$$\epsilon(D(h_1, h_2) = \Pr_{x \sim \mu(x)} [h_1(x) \neq h_2(x)].$$

**Theorem 2.** (Stone-Weierstrass Theorem [Stone (1937)]) Let $K$ be a compact subset of $\mathbb{R}^n$ and $f : K \rightarrow \mathbb{R}$ be a continuous function. Then, for every $\epsilon > 0$, there exists a polynomial, $P : K \rightarrow \mathbb{R}$, such that

$$\sup_{x \in K} |f(x) - P(x)| < \epsilon.$$

Theorem 2 indicates that continuous functions on a compact subset of $\mathbb{R}^n$ are approximated with polynomials. We next formulate the discrepancy of the two domains using the disagreement ratio and bound it with the label-wise moment divergence.

**Lemma 1.** Let $D$ and $D'$ be two domains over an input space $\mathcal{X} \subset \mathbb{R}^n$, where $n$ is the dimension of the inputs. Then, for any hypotheses $h_1, h_2 \in \mathcal{H}$ and any $\epsilon > 0$, there exist $n_\epsilon \in \mathbb{N}$ and a constant $a_{n_\epsilon}$, such that

$$|\epsilon(D(h_1, h_2) - \epsilon(D'(h_1, h_2))| \leq \frac{1}{2} a_{n_\epsilon} \sum_{k=1}^{n_\epsilon} d_{LM,k}(D, D') + \epsilon.$$

**Proof.** Let the domains $D$ and $D'$ have the data distribution of $\mu(x)$ and $\mu'(x)$, respectively, over an input space $\mathcal{X}$, which is a compact subset of $\mathbb{R}^n$, where $n$ is the dimension of the inputs. For brevity, we denote $|\epsilon(D(h_1, h_2) - \epsilon(D'(h_1, h_2))$ as $\Delta_{D, D'}$. Then,

$$\Delta_{D, D'} = |\epsilon(D(h_1, h_2) - \epsilon(D'(h_1, h_2))|
\leq \sup_{h_1, h_2 \in \mathcal{H}} |\epsilon(D(h_1, h_2) - \epsilon(D'(h_1, h_2))|
\leq \sup_{h_1, h_2 \in \mathcal{H}} \left| \Pr_{x \sim \mu(x)} [h_1(x) \neq h_2(x)] - \Pr_{x \sim \mu'(x)} [h_1(x) \neq h_2(x)] \right|
\leq \sup_{h_1, h_2 \in \mathcal{H}} \left| \int_{\mathcal{X}} \mu(x) 1_{h_1(x) \neq h_2(x)} dx - \int_{\mathcal{X}} \mu'(x) 1_{h_1(x) \neq h_2(x)} dx \right|.$$

For any hypotheses $h_1, h_2$, the indicator function $1_{h_1(x) \neq h_2(x)}$ is Lebesgue integrable on $\mathcal{X}$, i.e., $1_{h_1(x) \neq h_2(x)}$ is a $L^1$ function. Since a set of continuous functions is dense in $L^1(\mathcal{X})$, for every
\( \epsilon > 0 \), there exists a continuous \( L^1 \) function \( f \) defined on \( \mathcal{X} \) such that
\[
|1_{h_1(x) \neq h_2(x)} - f(x)| \leq \frac{\epsilon}{4}
\]
for every \( x \in \mathcal{X} \), and the fixed \( h_1 \) and \( h_2 \) that drive Equation 5 to the supremum. Accordingly,
\[
f(x) - \frac{\epsilon}{4} \leq 1_{h_1(x) \neq h_2(x)} \leq f(x) + \frac{\epsilon}{4}.
\]
By integrating every term in the inequality over \( \mathcal{X} \), the inequality,
\[
\int_{\mathcal{X}} \mu(x)f(x)dx - \frac{\epsilon}{4} \leq \int_{\mathcal{X}} \mu(x)1_{h_1(x) \neq h_2(x)}dx \leq \int_{\mathcal{X}} \mu(x)f(x)dx + \frac{\epsilon}{4},
\]
follows. Likewise, the same inequality on the domain \( \mathcal{D} \) by substituting the inequality in Equation 9 to the Equation 5, 
\[
\int_{\mathcal{D}} \mu(x)f(x)dx - \frac{\epsilon}{4} \leq \int_{\mathcal{D}} \mu(x)1_{h_1(x) \neq h_2(x)}dx \leq \int_{\mathcal{D}} \mu(x)f(x)dx + \frac{\epsilon}{4},
\]
is induced. By substituting the inequality in Equation 9 to the Equation 5,
\[
\Delta_{\mathcal{D}, \mathcal{D}'} \leq \left| \int_{\mathcal{D}} \mu(x)f(x)dx - \int_{\mathcal{D}'} \mu'(x)f(x)dx \right| + \frac{\epsilon}{2},
\]
By the Theorem 2 there exists a polynomial \( P(x) \) such that
\[
\sup_{x \in \mathcal{X}} |f(x) - P(x)| < \frac{\epsilon}{4},
\]
and the polynomial \( P(x) \) is expressed as
\[
P(x) = \sum_{k=1}^{n_k} \sum_{i \in \Delta_k} \alpha_i \prod_{j=1}^{n} (x_j)^{i_j},
\]
where \( n_k \) is the order of the polynomial, \( \Delta_k = \{i = (i_1, \ldots, i_n) \in \mathbb{N}_0^n | \sum_{j=1}^{n} i_j = k \} \) is the set of the tuples of the nonnegative integers, which add up to \( k \), \( \alpha_i \) is the coefficient of each term of the polynomial, and \( x = (x_1, x_2, \ldots, x_n) \). By applying Equation 11 to the Equation 10 and substituting the expression in Equation 12,
\[
\Delta_{\mathcal{D}, \mathcal{D}'} \leq \left| \int_{\mathcal{X}} \mu(x)P(x)dx - \int_{\mathcal{X}} \mu'(x)P(x)dx \right| + \epsilon
\]
\[
= \left| \int_{\mathcal{X}} \mu(x) \sum_{k=1}^{n_k} \sum_{i \in \Delta_k} \alpha_i \prod_{j=1}^{n} (x_j)^{i_j}dx - \int_{\mathcal{X}} \mu'(x) \sum_{k=1}^{n_k} \sum_{i \in \Delta_k} \alpha_i \prod_{j=1}^{n} (x_j)^{i_j}dx \right| + \epsilon
\]
\[
\leq \sum_{k=1}^{n_k} \sum_{i \in \Delta_k} |\alpha_i| \left| \int_{\mathcal{X}} \mu(x) \prod_{j=1}^{n} (x_j)^{i_j}dx - \int_{\mathcal{X}} \mu'(x) \prod_{j=1}^{n} (x_j)^{i_j}dx \right| + \epsilon
\]
\[
= \sum_{k=1}^{n_k} \sum_{i \in \Delta_k} |\alpha_i| \left| \int_{\mathcal{C}} \sum_{c \in \mathcal{C}} p(c) \mu_c(x) \prod_{j=1}^{n} (x_j)^{i_j}dx - \int_{\mathcal{C}} \sum_{c \in \mathcal{C}} p'(c) \mu'_c(x) \prod_{j=1}^{n} (x_j)^{i_j}dx \right| + \epsilon,
\]
where \( p(c) \) and \( p'(c) \) are the probability that an arbitrary data is labeled as class \( c \) in domain \( \mathcal{D} \) and \( \mathcal{D}' \), respectively, and \( \mu_c(x) = \mu(x|y = c) \) and \( \mu'_c(x) = \mu'(x|y = c) \) are the data distribution given
that the data is labeled as class \( c \) on domain \( D \) and \( D' \), respectively. For \( a_{\Delta_k} = \max_{i \in \Delta_k} |\alpha_i| \),

\[
\Delta_{D,D'} \leq \sum_{k=1}^{n_s} a_{\Delta_k} \sum_{i \in \Delta_k} \left| \int_X \sum_{c \in \mathcal{C}} p(c) \mu_c(x) \prod_{j=1}^{n} (x_j)^{i_j} dx - \int_X \sum_{c \in \mathcal{C}} p'(c) \mu'_c(x) \prod_{j=1}^{n} (x_j)^{i_j} dx \right| + \epsilon
\]

\[
\leq \sum_{k=1}^{n_s} a_{\Delta_k} \sum_{i \in \Delta_k} \sum_{c \in \mathcal{C}} p(c) \int_X \mu_c(x) \prod_{j=1}^{n} (x_j)^{i_j} - p'(c) \int_X \mu'_c(x) \prod_{j=1}^{n} (x_j)^{i_j} dx + \epsilon
\]

\[
\leq \sum_{k=1}^{n_s} a_{\Delta_k} d_{L,M,k}(D,D') + \epsilon
\]

\[
\leq \frac{1}{2} a_{n_s} \sum_{k=1}^{n_s} d_{L,M,k}(D,D') + \epsilon,
\]

for \( a_{n_s} = 2 \max_{1 \leq k \leq n_s} a_{\Delta_k} \). \( \square \)

Let \( N \) datasets be drawn from \( N \) labeled source domains \( S_1, S_2, \ldots, S_N \) respectively. We denote \( i \)-th source dataset \( X_{S_i} \) as \( \{(x_j^{S_i}, y_j^{S_i})\}_{j=1}^{n_{S_i}} \). The empirical error of hypothesis \( h \) in \( i \)-th source domain \( S_i \) estimated with \( X_{S_i} \) is formulated as \( \hat{\epsilon}_{S_i}(h) = \frac{1}{n_{S_i}} \sum_{j=1}^{n_{S_i}} 1_{h(x_j^{S_i}) \neq y_j^{S_i}} \). Given a positive weight vector \( \alpha = (\alpha_1, \alpha_2, \ldots, \alpha_N) \) such that \( \sum_{i=1}^{N} \alpha_i = 1 \) and \( \alpha_i \geq 0 \), the weighted empirical source error is formulated as \( \hat{\epsilon}_\alpha(h) = \sum_{i=1}^{N} \alpha_i \hat{\epsilon}_{S_i}(h) \).

**Lemma 2.** For \( N \) source domains \( S_1, S_2, \ldots, S_N \), let \( n_{S_i} \) be the number of samples from source domain \( S_i \), \( m = \sum_{i=1}^{N} n_{S_i} \) be the total number of samples from \( N \) source domains, and \( \beta = (\beta_1, \beta_2, \ldots, \beta_N) \) with \( \beta_i = \frac{n_{S_i}}{m} \). Let \( \epsilon_\alpha(h) \) be the weighted true source error which is the weighted sum of \( \epsilon_{S_i}(h) \) on domain \( \mathcal{H} \) for every \( i = 1, 2, \ldots, N \). We define \( \hat{\epsilon}_\alpha(h) = \sum_{i=1}^{N} \alpha_i \hat{\epsilon}_{S_i}(h) \).

\[
\Pr \left[ \left| \hat{\epsilon}_\alpha(h) - \epsilon_\alpha(h) \right| \geq \epsilon \right] \leq 2 \exp \left( -\frac{2m\epsilon^2}{\sum_{i=1}^{N} \frac{\alpha_i^2}{\beta_i}} \right)
\]  

(21)

**Proof:** It has been proven in Ben-David et al. (2010). \( \square \)

We now turn our focus back to the Theorem [1] in the paper and complete the proof.

**Theorem 1.** Let \( \mathcal{H} \) be a hypothesis space of VC dimension \( d \), \( n_{S_i} \) be the number of samples from source domain \( S_i \), \( m = \sum_{i=1}^{N} n_{S_i} \) be the total number of samples from \( N \) source domains \( S_1, \ldots, S_N \), and \( \beta = (\beta_1, \ldots, \beta_N) \) with \( \beta_i = \frac{n_{S_i}}{m} \). Let us define a hypothesis \( \hat{h} = \arg \min_{h \in \mathcal{H}} \epsilon_\alpha(h) \) that minimizes the weighted empirical source error, and a hypothesis \( h_T^* = \arg \min_{h \in \mathcal{H}} \epsilon_T(h) \) that minimizes the true target error. Then, for any \( \delta \in (0, 1) \) and \( \epsilon > 0 \), there exist \( N \) integers \( n_1, \ldots, n_N \) and \( N \) constants \( a_{n_1}, \ldots, a_{n_N} \) such that

\[
\epsilon_T(\hat{h}) \leq \epsilon_T(h_T^*) + \eta_{\alpha,\beta,m,\delta} + \epsilon + \sum_{i=1}^{N} \alpha_i \left( \frac{2\lambda_i}{a_{n_i}} \right) \sum_{k=1}^{n_i} d_{L,M,k}(S_i, T)
\]

(22)

with probability at least \( 1 - \delta \), where \( \eta_{\alpha,\beta,m,\delta} = 4 \sqrt{\sum_{i=1}^{N} \frac{\alpha_i^2}{\beta_i}} \left( \frac{d(\log\left( \frac{2m}{\delta} \right) + 1) + 2 \log\left( \frac{1}{\delta} \right) }{m} \right) \) and \( \lambda_i = \min_{h \in \mathcal{H}} \epsilon_T(h) + \epsilon_{S_i}(h) \).

**Proof:**

\[
|\epsilon_\alpha(h) - \epsilon_T(h)| = \sum_{i=1}^{N} \alpha_i |\epsilon_{S_i}(h) - \epsilon_T(h)| \leq \sum_{i=1}^{N} \alpha_i |\epsilon_{S_i}(h) - \epsilon_T(h)|.
\]

(23)

We define \( h_T^* = \arg \min_{h \in \mathcal{H}} \epsilon_{S_i}(h) + \epsilon_T(h) \) for every \( i = 1, 2, \ldots, N \) for the following equations.

We also note that the 1-triangular inequality (Crammer et al. 2008) holds for binary classification...
tasks, i.e., $\epsilon_D(h_1, h_2) \leq \epsilon_D(h_1, h_3) + \epsilon_D(h_2, h_3)$ for any hypothesis $h_1, h_2, h_3 \in \mathcal{H}$ and domain $\mathcal{D}$. Then,

$$|\epsilon_D(h) - \epsilon_D(h, h')| = |\epsilon_D(h, D) - \epsilon_D(h, h')| \leq \epsilon_D(D, h') = \epsilon_D(h')$$

(24)

for the ground truth labeling function $l_D$ on the domain $\mathcal{D}$ and two hypotheses $h, h' \in \mathcal{H}$. Applying the definition and the inequality to Equation 17,

$$|\epsilon_h - \epsilon_T(h)| \leq \sum_{i=1}^{N} \alpha_i \left( |\epsilon_S(h) - \epsilon_S(h, h_i^*)| + |\epsilon_S(h, h_i^*) - \epsilon_T(h, h_i^*)| + |\epsilon_T(h, h_i^*) - \epsilon_T(h)| \right)$$

$$\leq \sum_{i=1}^{N} \alpha_i \left( \epsilon_S(h, h_i^*) - \epsilon_T(h, h_i^*) + \epsilon_T(h_i^*) \right)$$

(25)

By the definition of $h_i^*, \epsilon_S(h, h_i^*) + \epsilon_T(h_i^*) = \lambda_i$ for $\lambda_i = \min_{h \in \mathcal{H}} \{ \epsilon_T(h) + \epsilon_S(h) \}$. Additionally, according to Lemma 1 for any $\epsilon > 0$, there exists an integer $n_\epsilon$ and a constant $a_{n_\epsilon^*}$ such that

$$|\epsilon_S(h, h_i^*) + \epsilon_T(h_i^*)| \leq \frac{1}{2} a_{n_\epsilon^*} \sum_{k=1}^{n_i^*} d_{LM,k}(S_i, T) + \frac{\epsilon}{2}.$$ 

(26)

By applying these relations,

$$|\epsilon_h - \epsilon_T(h)| \leq \sum_{i=1}^{N} \alpha_i \left( \lambda_i + \frac{1}{2} a_{n_\epsilon^*} \sum_{k=1}^{n_i^*} d_{LM,k}(S_i, T) + \frac{\epsilon}{2} \right)$$

$$\leq \sum_{i=1}^{N} \alpha_i \left( \lambda_i + \frac{1}{2} a_{n_\epsilon^*} \sum_{k=1}^{n_i^*} d_{LM,k}(S_i, T) \right) + \frac{\epsilon}{2}.$$ 

(27)

By Lemma 2 and the standard uniform convergence bound for hypothesis classes of finite VC dimension (Ben-David et al. 2010),

$$\epsilon_T(h) \leq \epsilon_h(h) + \frac{\epsilon}{2} + \sum_{i=1}^{N} \alpha_i \left( \lambda_i + \frac{1}{2} a_{n_\epsilon^*} \sum_{k=1}^{n_i^*} d_{LM,k}(S_i, T) \right)$$

$$\leq \epsilon_h(h) + \frac{1}{2} \eta_{h, \alpha, m, \delta} + \frac{\epsilon}{2} + \sum_{i=1}^{N} \alpha_i \left( \lambda_i + \frac{1}{2} a_{n_\epsilon^*} \sum_{k=1}^{n_i^*} d_{LM,k}(S_i, T) \right)$$

$$\leq \epsilon_h(h^*_T) + \frac{1}{2} \eta_{h, \alpha, \beta, m, \delta} + \frac{\epsilon}{2} + \sum_{i=1}^{N} \alpha_i \left( \lambda_i + \frac{1}{2} a_{n_\epsilon^*} \sum_{k=1}^{n_i^*} d_{LM,k}(S_i, T) \right)$$

(28)

$$\leq \epsilon_h(h^*_T) + \eta_{h, \alpha, \beta, m, \delta} + \frac{\epsilon}{2} + \sum_{i=1}^{N} \alpha_i \left( \lambda_i + \frac{1}{2} a_{n_\epsilon^*} \sum_{k=1}^{n_i^*} d_{LM,k}(S_i, T) \right)$$

$$\leq \epsilon_T(h^*_T) + \eta_{h, \alpha, \beta, m, \delta} + \frac{\epsilon}{2} + \sum_{i=1}^{N} \alpha_i \left( 2 \lambda_i + a_{n_\epsilon^*} \sum_{k=1}^{n_i^*} d_{LM,k}(S_i, T) \right).$$

The last inequality holds by Equation 21 with $h = h^*_T$. \qed
A.2 Summary of Datasets

Table 3: Summary of datasets.

| Digits-Five  | Features | Labels | Training set | Test set | Properties       |
|--------------|----------|--------|--------------|----------|------------------|
| MNIST        | 1x28x28  | 10     | 60000        | 10000    | Grayscale images |
| MNIST-M      | 3x32x32  | 10     | 59001        | 9001     | RGB images       |
| SVHN         | 3x32x32  | 10     | 73257        | 26032    | RGB images       |
| SynthDigits  | 3x32x32  | 10     | 479400       | 9553     | RGB images       |
| USPS         | 1x16x16  | 10     | 7291         | 2007     | Grayscale images |

| Office-Caltech10 | Features | Labels | Training set | Test set | Properties       |
|------------------|----------|--------|--------------|----------|------------------|
| Amazon           | 3x300x300| 10     | 958          | 958      | RGB images       |
| Caltech          | Variable | 10     | 1123         | 1123     | RGB images       |

| Webcam           | Variable | 10     | 295          | 295      | RGB images       |

| Amazon Reviews  |          |        |              |          |                  |
| Books           | 5000     | 2      | 2000         | 4465     | 5000-dim vector  |
| DVDs            | 5000     | 2      | 2000         | 3586     | 5000-dim vector  |
| Electronics     | 5000     | 2      | 2000         | 5681     | 5000-dim vector  |
| Kitchen appliances | 5000 | 2      | 2000         | 5945     | 5000-dim vector  |

A.3 Qualitative Analysis for EnMDAP

We investigate how our approaches transform the features extracted by \( f_c \). We embed the extracted features on 2D space using t-SNE (Maaten & Hinton (2008)) as shown in Figure A.3. We visualize 3200 target features and the label of each data is denoted by a distinct color. The features extracted without any adaptation and the features of MDAP-L are mingled regardless of the labels. The features of MDAP and EnMDAP with \( n=2,3 \), on the other hand, are much less ambiguous. The difference shows the efficacy of the label-wise moment matching in our methods; it separates the features with different labels and agglomerates the features with the same labels. The cluster assumption states that low-density separation between classes improves generalization performance, i.e., the features with different labels should be thoroughly separated for better classification accuracy (Chapelle & Zien (2005); Lee (2013)). Therefore, EnMDAP’s feature extractors, which draw the features with the same labels together while separating the different labels, are crucial elements in its superior performance.
