Abstract

Information-based Bayesian optimization (BO) algorithms have achieved state-of-the-art performance in optimizing a black-box objective function. However, they usually require several approximations or simplifying assumptions (without clearly understanding their effects on the BO performance) and/or their generalization to batch BO is computationally unwieldy, especially with an increasing batch size. To alleviate these issues, this paper presents a novel trusted-maximizers entropy search (TES) acquisition function: It measures how much an input query contributes to the information gain on the maximizer over a finite set of trusted maximizers, i.e., inputs optimizing functions that are sampled from the Gaussian process posterior belief of the objective function. Evaluating TES requires either only a stochastic approximation with sampling or a deterministic approximation with expectation propagation, both of which are investigated and empirically evaluated using synthetic benchmark objective functions and real-world optimization problems, e.g., hyperparameter tuning of a convolutional neural network and synthesizing ‘physically realizable’ faces to fool a black-box face recognition system. Though TES can naturally be generalized to a batch variant with either approximation, the latter is amenable to be scaled to a much larger batch size in our experiments.

1 INTRODUCTION

Bayesian optimization (BO) is an effective strategy for iteratively obtaining noisy outputs at input queries of an objective function to efficiently learn about the input locations of its maximum value, i.e., its maximizers, regardless of the function’s closed-form expression, derivatives, or convexity [Brochu et al., 2010b, Shahriari et al., 2015]. It is particularly useful when the budget of function evaluations is limited due to time/monetary costs such as in the design [Brochu et al., 2010a] and machine learning model training [Snoek et al., 2012, Dai et al., 2019]. There has been a rapid growth in the number of works generalizing BO to nonmyopic BO [Ling et al., 2016], high-dimensional BO [Hoang et al., 2018], private outsourced BO [Kharkovskii et al., 2020], multi-fidelity BO [Zhang et al., 2017, 2019], recursive reasoning BO [Dai et al., 2020], and ranking BO [Nguyen et al., 2021b].

On the other hand, restricting a BO solution to only one input query at each iteration cannot take advantage of parallel function evaluations which are becoming increasingly attainable due to, for example, the rapid growth of computing resources’ affordability and availability these days. In such a scenario and the time constraint, the urge to obtain the noisy outputs at a batch of input queries, i.e., batch Bayesian optimization, becomes prominent. However, this task is challenging due to the extra modifications needed to account for correlation in a batch such as, seen in several existing works [Ginsbourger et al., 2010, Desautels et al., 2014, Shah and Ghahramani, 2015, González et al., 2016, Daxberger and Low, 2017]. It encourages the development of BO algorithms that can be naturally generalized to the batch scenario without making additional adjustments.

To approach this problem, this paper focuses on information-based BO acquisition functions. In particular, it is the information gain about the maximizer (or the maximum value) of the objective function through observing noisy function outputs at input queries. This definition is much the same in spite of the number of input queries at each BO iteration, e.g., a single query or a batch of queries. The essence of these acquisition functions is different from upper confidence bound (UCB) that UCB minimizes the regret (over function outputs at evaluated inputs), while information-based acquisitions aim to infer the maximizer’s location regardless of the function outputs at the evaluated inputs.
They also have a distinctive feature from other heuristic acquisition functions such as probability of improvement [Kushner, 1964] and expected improvement (EI) [Mockus et al., 1978]. It is about capturing the knowledge/belief of the maximizer (or the maximum value) over the whole input space (a global measure), which cannot be done with local heuristics, as argued in the work of [Hennig and Schuler, 2012]. Empirically, these information-based acquisition functions such as predictive entropy search (PES) have shown notable success in optimizing black-box functions [Hernández-Lobato et al., 2014].

In this paper, we take a different approach in constructing the trusted-maximizers entropy search (TES) acquisition function that (1) intuitively conveys the notion of maximizer without directly evaluating the information gain of the global maximizer; and (2) is amenable to batch BO. The first property is made feasible by the observation: while being the global maximizer requires its function output to be not less than those evaluated at all other inputs in the function’s domain, it is much easier to eliminate an input as the global maximizer which requires the existence of only an input whose function output is larger. Hence, if we can construct a set of “promising” inputs to be the maximizer, refining this set by rejecting its inputs can effectively refine the belief of the maximizer. The second property comes from the fact that our approximation does not depend on the input queries, hence considering a batch of input queries does not increase the approximation’s complexity. Both stochastic and deterministic approximations are examined in the paper, and their empirical performances are illustrated using synthetic benchmark objective functions and real-world optimization problems, e.g., hyperparameter tuning of a convolutional neural network and synthesizing “physically realizable” faces to fool a black-box face recognition system.

2 RELATED WORKS

Most of the existing information-based works are centered around an intuitive measure of the information gain of the maximizer of the objective function, e.g., entropy search (ES) [Hennig and Schuler, 2012] and PES [Hernández-Lobato et al., 2014]. While ES selects an input query by directly maximizing the information gain on the maximizer via reducing the maximizer’s entropy, it requires a series of approximations. On the other hand, PES exploits the symmetric property of mutual information to sidestep the approximations in ES, and yet, it requires computing a predictive belief that involves an intractable constraint. In our view, these approaches’ inherent difficulty is rooted in the modeling of the objective function’s global maximizer as an input whose function output is not less than those evaluated at other inputs in the domain. Imposing exactly this condition is hardly feasible as it involves the whole input space. Therefore, we would like to develop TES that does not require such a condition.

There are exceptions that focus on the information gain of the maximum value of the objective function such as output-space predictive entropy search [Hoffman and Ghahramani, 2015], max-value entropy search (MES) [Wang and Jegelka, 2017], fast information-theoretic Bayesian optimization [Ru et al., 2018], and binary entropy search for maximum value prediction [Nguyen et al., 2021a] which result in a simpler approximation, e.g., MES enjoys a closed-form expression. However, as admitted by MES’s authors, it is not intuitive that the information of the maximum value is a good search strategy for the maximizer.

Regarding the batch BO problem, there have been several works in the existing literature such as q-EI with a constant liar strategy (QEI-CL) [Ginsbourger et al., 2010], Gaussian process batch upper confidence bound (BUCB) [De-sautels et al., 2014], QEI [Marmin et al., 2015], batch BO via local penalization (BBO-LP) [González et al., 2016], and parallel predictive entropy search (PPES) [Shah and Ghahramani, 2015]. However, QEI-CL, BUCB, and LP-EI optimize greedily each input one by one in the batch based on a heuristic value at input queries (QEI-CL), or purely based on the predictive variance to encourage exploration (BUCB), or based on a local penalty based on an estimation of the objective function’s Lipschitz constant (LP-EI).

On the other hand, QEI and PPES are able to optimize the batch jointly, which is also a property of the proposed TES acquisition function in this paper. It is noted that only PPES is an acquisition function that is based on the information gain. While it is extended from the computationally efficient PES [Hernández-Lobato et al., 2014], the optimization of PPES requires a computationally expensive inner loop of expectation propagation (EP). To the best of our knowledge, there have not been any batch BO solution extended from MES. It is probably because a direct extension of MES to a batch variant requires computing the entropy of a truncated multivariate Gaussian random variable.

3 PROBLEM SETUP

We propose a BO algorithm for black-box optimization problems, where the analytical form or the derivative information of the objective function are unknown. Given a black-box function \( f : \mathcal{X} \to \mathbb{R} \), we search for the global maximizer \( x^* \triangleq \max_{x \in \mathcal{X}} f(x) \) in an iterative manner. At each iteration, the BO algorithm is required to select input queries based on the posterior belief of \( f \) given all observations \( y = (y_x)_{x \in D} \) at preceding input queries \( D \subset \mathcal{X} \) where \( y_x \triangleq f(x) + \epsilon \) and \( \epsilon \sim \mathcal{N}(0, \sigma_x^2) \). These input queries are selected to improve the belief of \( x^* \) as much as possible. Specifically, BO models the posterior belief of \( f \) by a GP with the function’s prior mean \( \mathbb{E}[f(x)] \) and covariance \( k_{xx'} \triangleq \text{cov}(f(x), f(x')) \) for all \( x, x' \in \mathcal{X} \). The covariance is constructed with the squared exponential
where its hyperparameters include the length-scales
\[ \sigma^2 \exp(-0.5(x - x')^T \Lambda^{-2}(x - x')) \]
where its hyperparameters include the length-scales \( \Lambda \triangleq \text{diag}[\ell_1, \ldots, \ell_d] \) and the signal variance \( \sigma^2 \). The prior mean is usually set to zero to simplify the equations. Given \( y_D \), the predictive distributions of \( f(x) \) and \( \beta_x \) are Gaussian distributions: \( p(f(x)|y_D) \sim \mathcal{N}(\mu_x, \sigma^2_x) \) and \( p(y_x|y_D) \sim \mathcal{N}(\mu_x, \sigma^2_x + \sigma^2_n) \), respectively, where
\[
\begin{align*}
\mu_x & \triangleq K_{xD}(K_{DD} + \sigma^2_n I)^{-1}y_D \\
\sigma_x^2 & \triangleq k_{xx} - K_{xD}(K_{DD} + \sigma^2_n I)^{-1}K_{Dx},
\end{align*}
\]
(1)

\( K_{xD} \triangleq (k_{xx'})_{x',D} \), \( K_{DD} \triangleq (k_{xx'}')_{x',x''} \in D \), \( I \) is the identity matrix, and \( K_{Dx} \triangleq K_{x,D}^T \).

## 4 TRUSTED-MAXIMIZERS ENTROPY SEARCH

Information-based acquisition functions, like ES ([Hennig and Schuler, 2012] and PES ([Hernández-Lobato et al., 2014]) have been designed to enable their BO algorithms to improve the (posterior) belief \( p(x^*|y_D) \triangleq p(f(x^*) = \max_{x \in X} f(x)|y_D) \) of the global maximizer \( x^* \) of the objective function \( f \). In particular, ES can be directly used to measure the information gain on \( x^* \) by selecting the next input query \( x \) for evaluating \( f \) given the noisy observations \( y_D \) from the previous BO iterations:
\[
\alpha(y_D, x) \triangleq H(x^*|y_D) - \mathbb{E}_{p(y_x|y_D)}[H(x^*|y_{D\cup\{x\}})] .
\]
(2)

However, evaluating (2) requires a series of approximations. Furthermore, one of them incurs cubic time in the size of the discretized input domain and thus it becomes expensive with a large input domain (or risks (2) being approximated poorly). To sidestep these issues, PES exploits the symmetric property of mutual information to re-express (2) as
\[
\alpha(y_D, x) = H(y_x|y_D) - \mathbb{E}_{p(x^*|y_D)}[H(y_x|y_{D\cup\{x\}})].
\]
(3)

Intuitively, the selection of an input query \( x \) to maximize (3) has to trade-off between exploration (hence inducing a large Gaussian predictive entropy \( H(y_x|y_D) \)) vs. exploitation of the current posterior belief \( p(x^*|y_D) \) of \( x^* \) to choose a nearby input of \( f \) to be evaluated (hence inducing a small expected predictive entropy \( \mathbb{E}_{p(x^*|y_D)}[H(y_x|y_{D\cup\{x^*\}})] \)) to yield a highly informative observation that in turn improves the posterior belief of \( x^* \). Computing the predictive belief \( p(y_x|y_D, x^*) \) necessary for the second entropy term in (3) requires incorporating the constraint of \( f(x^*) \geq f(x) \) for all \( x \in X \) which unfortunately is not tractable without imposing simplifying assumptions. It is not clear to which extent they would compromise the quality of the resulting approximation of the predictive belief \( p(y_x|y_D, x^*) \). The work of [Wang and Jegelka, 2017] proposed using the information gain on the global maximum \( f(x^*) \) but admitted that it is not intuitive why it would necessarily be a good surrogate of that on the global maximizer \( x^* \). Therefore, this paper still focuses on finding \( x^* \), albeit with a new perspective that is different from ES and PES, which we will discuss next.

Let \( X^* \subset X \) denote a finite set of trusted maximizers, i.e., inputs that are more likely to be the global maximizer \( x^* \) in the current BO iteration, that is, \( p(x^* \in X^*|y_D) \) is large. Let \( x^* \) be a r.v. representing the maximizer of \( f \) over \( X^* \), that is, \( p(x^*|y_D) \triangleq p(f(x^*) = \max_{x \in X^*} f(x)|y_D) \). To ease the exposition of our key idea here, we consider a unique maximizer of \( f \) over \( X^* \) but do not assume this when we describe our technical approach later. By finding the maximizer \( x^* \) of \( f \) over \( X^* \), it effectively eliminates the remaining input queries in \( X^* \setminus \{x^*\} \) from being the global maximizer \( x^* \) because \( f(x^*) > f(x) \) for all \( x \in X^* \setminus \{x^*\} \). So, if \( p(x^* \in X^*|y_D) \) is large, then eliminating some input queries in \( X^* \) would gain us useful information on the global maximizer \( x^* \). Furthermore, besides reducing the probability of each input query \( x \in X^* \setminus \{x^*\} \) being \( x^* \), their neighboring input queries also experience a reduced probability of being \( x^* \). We illustrate this with a simple example of input dimension \( d = 1 \) in Fig. 1i. Let \( x^* \in [0, 1.4] \) and \( x^* \in [1.6, 3] \). It can be observed that by conditioning on only \( f(1) > f(2) \), the probability of \( f(x^*) > f(x^*) \) in Fig. 1i (hence implying \( f(x^*) > f(x^*) \)) increases from that of 0.5 in Fig. 1i. In other words, the probability of \( x^* \in [1.6, 3] \) being \( x^* \) reduces. The magnitude of reduction depends on the correlation between \( f(x) \) and the outputs of \( f \) evaluated at the input queries in \( [1.6, 3] \), which in turn depends on the length-scale of the SE kernel (see Fig. 1i).

So, if we can construct the set \( X^* \) of trusted maximizers such that \( p(x^* \in X^*|y_D) \) is large, then finding the maximizer \( x^* \) of \( f \) over \( X^* \) would gain us useful information on the global maximizer \( x^* \) since it reduces the probability of each input query \( x \in X^* \setminus \{x^*\} \) and its neighbors being \( x^* \), as explained above. We therefore form \( X^* \) using samples of \( x^* \) drawn from the posterior belief \( p(x^*|y_D) \): To do this, we adopt the method of [Hernández-Lobato et al., 2014] to first approximately sample \( x^* \) functions from the GP predictive belief given \( y_D \) and then compute the global maximizers of these sampled functions to form \( X^* \).

Given the set \( X^* \) of trusted maximizers computed in the current BO iteration, our trusted-maximizers entropy search (TES) acquisition function is designed to enable its BO algorithm to find the maximizer \( x^* \) of \( f \) over \( X^* \) by improving the posterior belief \( p(x^*|y_D) \). Specifically, TES measures the information gain on \( x^* \) by selecting the next input query \( x \in X \) for evaluating \( f \) given the noisy observations \( (D, y_D) \) from the previous BO iterations:
\[
\alpha(y_D, x) \triangleq H(x^*|y_D) - \mathbb{E}_{p(y_x|y_D)}[H(x^*|y_{D\cup\{x\}})].
\]
(4)

Since the second entropy term in (4) requires the posterior belief \( p(x^*|y_{D\cup\{x\}}) \) to be computed for prohibitively
Since $p(f_{x^*} | y_D, x^*)$ cannot be evaluated in closed form, we approximate it with either (a) sampling whose approximation quality improves with the number of samples or (b) a Gaussian distribution to make $p(y_k | y_D, x^*)$ Gaussian. These two approximation methods are discussed next.

**Remark 2.** Since $p(f_{x^*} | y_D, x^*)$ does not depend on the input query $x$, its approximation remains unchanged when our TES acquisition function (5) is optimized with respect to the input query $x \in X$ in each BO iteration, that is, $\max_{x \in X} \alpha^*(y_D, x)$. So, $p(f_{x^*} | y_D, x^*)$ is approximated only once in each BO iteration, which simplifies the optimization procedure and facilitates an efficient generalization to batch BO (Section 4.3). In contrast, the approximations needed to derive PPES and ES depend on $x$ and hence have to be repeated for every $x \in X$ to optimize PPES and ES.

We will discuss the evaluation of TES by both stochastic approximation with sampling, denoted as TES$_{sp}$, and deterministic approximation with expectation propagation (EP), denoted as TES$_{ep}$, as below.

### 4.1 STOCHASTIC APPROXIMATION WITH SAMPLING

Let $F_{x^*}$ denote a set of samples that are randomly drawn from $p(f_{x^*} | y_D, x^*)$. This can be obtained via rejection sampling by drawing samples from the GP predictive belief $p(f_{x^*} | y_D)$ and rejecting those samples of $f_{x^*}$ where $\max_{x^* \in X} f(x^*) > f(x^{\star})$. However, if $p(x^* | y_D)$ is small, then such a sampling becomes inefficient due to a large number of rejected samples. Importance sampling can be used to avoid this issue. Let $f_{x^*} \overset{\text{iid}}{\sim} (f(x^*))^T \in X^{\star}$,(x^*). Then,

$$p(f_{x^*} | y_D, x^*) \propto p(f_{x^*}, x^* | y_D) = p(x^* | f_{x^*}, y_D) p(f_{x^*} | y_D) = (f(x^*))^T f_{x^*} | y_D, x^* .$$

We first draw samples of $f_{x^*}$ from $p(f_{x^*} | y_D)$ and then weight these samples by $p(x^* | f_{x^*}, y_D) = 1 - \Phi(f(x^*) | f_{x^*}, y_D)(f^+) = \max_{x \in X^*} | (x^*) (x^*) | f(x^*)$ and $\Phi(f(x^*), y_D)(f^+)$ is the cumulative distribution function (c.d.f.) of the GP predictive belief $p(f(x^*) | f_{x^*}, y_D)$ evaluated at $f^+$. The details of importance sampling are given in Appendix B.

Alternatively, if the number of samples to be drawn from $p(f_{x^*} | y_D, x^*)$ is allowed to vary for different $x^*$, then we can simply draw samples from the GP predictive belief $p(f_{x^*} | y_D)$ and group them based on their maximizers. This may result in no sample for some $x^*$, especially if $p(x^* | y_D)$ is small. In this case, we simply update $X^*$ to omit such $x^*$. It follows from Remark 2 that the construction of $F_{x^*}$ does not depend on the input query $x$ and is hence performed only once in each BO iteration.

### 4.2 DETERMINISTIC APPROXIMATION WITH EP

Given $F_{x^*, y_D, X^*}$, $p(y_k | y_D, x^*)$ in (6) can be approximated by $q_{sp}(y_k | y_D, x^*) \overset{\text{d}}{=} |F_{x^*}|^{-1} \sum_{f_{x^*} \in F_{x^*}} p(y_k | f_{x^*})$, where $q_{sp}(y_k | y_D, x^*)$ is a Gaussian of variance $\sigma$.

### 4.3 ADDITIONAL Remarks

These two approximation methods are discussed next.
where the GP predictive belief \( p(y_{k}|f_{X}, y_{D}) \) is derived in Appendix\[C\] Then, TES_{sp} can be evaluated as follows

\[
\alpha_{sp}(y_{D}, x) \equiv |\mathcal{F}_{x^{*}}|^{-1} \sum_{x^{*} \in \mathcal{F}_{x^{*}}} p(\mathcal{x}^{*}|y_{D}) \sum_{f_{x^{*}} \in \mathcal{F}_{x^{*}}} \mathbb{E}_{p(y_{k}|f_{x^{*}, y_{D}})}(\log q_{sp}(y_{k}|y_{D}, x^{*}) - \log q_{sp}(y_{k}|y_{D}))
\]

where \( q_{sp}(y_{k}|y_{D}) \equiv \sum_{x^{*} \in \mathcal{X}^{*}} p(x^{*}|y_{D}) q_{sp}(y_{k}|x^{*}, y_{D}, x^{*}) \). It is amenable to stochastic optimization with respect to \( x \) via stochastic gradients which are derived using mini-batches of \( y_{k} \) randomly sampled from the GP predictive belief \( p(y_{k}|f_{X^{*}}, y_{D}) \) for all \( f_{x^{*}} \in \mathcal{F}_{x^{*}} \).

Given \( \mathcal{X}^{*} \), the time complexity to evaluate \( \alpha_{sp}(y_{D}, x) \) is \( O(|\mathcal{D}|^2|\mathcal{X}^{*}| + |\mathcal{F}_{x^{*}}||\mathcal{X}^{*}|^2 + |\mathcal{X}^{*}|^3 + (|\mathcal{X}^{*}| + |\mathcal{D}|)^3) \) where \( O(|\mathcal{D}|^2|\mathcal{X}^{*}|) \) is the time complexity of the GP prediction at \( \mathcal{X}^{*} \) given \( y_{D} \). \( O(|\mathcal{F}_{x^{*}}||\mathcal{X}^{*}|^2 + |\mathcal{X}^{*}|^3) \) is the time complexity of sampling \( \mathcal{F}_{x^{*}} \), and \( O((|\mathcal{X}^{*}| + |\mathcal{D}|)^3) \) is the time complexity of evaluating \( p(y_{k}|f_{X^{*}}, y_{D}) \).

### 4.2 Deterministic Approximation with Expectation Propagation (EP)

Alternatively, we can approximate \( p(f_{X^{*}}|y_{D}, x^{*}) \) with a Gaussian distribution so that \( p(y_{k}|y_{D}, x^{*}) \) can be evaluated in closed form. Compared with the above sampling method, its approximation cannot be refined due to its restriction to a Gaussian (see Fig. [2]). Nevertheless, it is time- and memory-efficient. Its approximation is performed by matching the moments: The mean and covariance of the Gaussian distribution are the same as that of \( p(f_{X^{*}}|y_{D}, x^{*}) \) being approximated. To do this, one can compute the empirical mean and covariance of the samples in \( \mathcal{F}_{x^{*}} \). An alternative without the sampling of \( p(f_{X^{*}}|y_{D}, x^{*}) \) is EP [Minka, 2001] which approximates \( p(f_{X^{*}}|y_{D}, x^{*}) \) with a Gaussian \( q_{ep}(f_{X^{*}}|y_{D}, x^{*}) \equiv \mathcal{N}(\mu_{ep}, \Sigma_{ep}) \), as detailed in Appendix [D]. It follows from Remark 2 that \( q_{ep}(f_{X^{*}}|y_{D}, x^{*}) \) does not depend on the input query \( x \) and is hence computed only once in each BO iteration. Consequently, \( p(y_{k}|y_{D}, x^{*}) \) can be approximated in closed form with a Gaussian:

\[
q_{ep}(y_{k}|y_{D}, x^{*}) \equiv \mathcal{N}(a^{T}\mu_{ep} + b, \sigma_{\epsilon|\mathcal{X}^{*}}^{2} + a^{T}\Sigma_{ep}a + \sigma_{\epsilon|\mathcal{X}^{*}}^{2})
\]

where the posterior variance \( \sigma_{\epsilon|\mathcal{X}^{*}}^{2} \) of the GP predictive belief \( p(f(x)|f_{X^{*}}, y_{D}) \), \( a, \) and \( b \) are given in Appendix\[E\]. Then, TES_{ep} can be evaluated as follows

\[
\alpha_{ep}(y_{D}, x) \equiv \sum_{x^{*} \in \mathcal{X}^{*}} p(x^{*}|y_{D}) \mathbb{E}_{q_{ep}(y_{k}|y_{D}, x^{*})}(\log q_{ep}(y_{k}|y_{D}, x^{*}) - \log q_{ep}(y_{k}|y_{D}))
\]

where \( q_{ep}(y_{k}|y_{D}) \equiv \sum_{x^{*} \in \mathcal{X}^{*}} p(x^{*}|y_{D}) q_{ep}(y_{k}|x^{*}, y_{D}, x^{*}) \). Hence, it is amenable to stochastic optimization like the optimization of \( \alpha_{ep}(y_{D}, x) \).

### 4.3 Analysis

Given \( \mathcal{X}^{*} \), the time complexity of evaluating \( \alpha_{ep}(y_{D}, x) \) is mainly due to the EP procedure which incurs \( O(n_{ep}|\mathcal{X}^{*}| |\mathcal{D}|^3) \) where \( n_{ep} \) is the number of EP iterations.

Fig. [3] shows different acquisition functions in a synthetic example. Recall that TES measures the information gain on \( x^{*} \in \mathcal{X}^{*} \) by selecting the next input query \( x \in \mathcal{X} \) for evaluating \( f \). So, for any \( x \) that is far from \( \mathcal{X}^{*} \), \( f(x) \) has little correlation with \( f_{X^{*}} \), and its TES value should be close to 0. This observation holds for TES_{sp} and TES_{ep} in Fig. [3]. Furthermore, TES_{sp} and TES_{ep} select an input in \( \mathcal{X}^{*} \) when \( f_{X^{*}} \) are not strongly correlated, as shown in Fig. [3b]; red crosses are input queries \( x \) that optimize the acquisition functions. When there is a strong correlation within \( f_{X^{*}} \), TES_{sp} and TES_{ep} can exploit the correlation to select an informative input query \( x \) around \( \mathcal{X}^{*} \), as shown in Fig. [3a]. As a result, to optimize TES, we should initialize the optimization with inputs in \( \mathcal{X}^{*} \). Another observation is that TES_{ep} exploits more than TES_{sp}, as shown in Appendix\[F\].
In batch BO where a batch of inputs, denoted as $\mathcal{B}$, is selected at each BO iteration, TES is defined as the amount of information gain about $x^*$ through observing the noisy observations $y_B$ of the batch $\mathcal{B}$:

$$
\alpha^*(y_D, B) = H(y_B | y_D) - \mathbb{E}_{p(x^* | y_D)}[H(y_B | y_D, x^*)]
$$

It can be approximated either stochastically with samples or deterministically with EP. The Gaussian predictive entropy $H(y_B | y_D)$ naturally encourages the diversity of a batch, e.g., sampling of highly correlated observations in a batch (i.e., redundant information) is discouraged. This is different from several existing works such as BBO-LP [González et al., 2016] which requires a local penalization term based on the objective function’s Lipschitz constant in addition to the acquisition function. Increasing the batch size from one (in the previous section) to multiple input queries changes neither the set of samples $\mathcal{F}_x$, approximating $p(f_X | y_D, x^*)$ in the stochastic approximation nor the approximate posterior $q_{ep}(f_X | y_D, x^*)$ for $p(f_X | y_D, x^*)$ in the deterministic approximation. Both approximations are applied in the same manner as those in the previous section (i.e., only once prior to the acquisition optimization in each BO iteration). The only difference in batch BO for $|\mathcal{B}| > 1$ is that $y_B$ is a multivariate r.v., so $q_{ep}(y_B | y_D, x^*)$ and $q_{ep}(y_B | y_D, x^*)$ are a mixture of multivariate Gaussian distributions and a multivariate Gaussian distribution, respectively. Still, samples of $y_B$ from these distributions can be drawn efficiently for the stochastic optimization of the acquisition function.

Batch TES with more than one input in the batch still exhibits similar behavior to that with only one input in the batch. That is, when $f_{x^*}$ are not strongly correlated, a sensible strategy is to sample observations at inputs in $x^*$ to identify $x^*$ (the right column of Fig. 4). In contrast, when there is a strong correlation in $f_{x^*}$, TES can exploit the correlation to sample informative observations at inputs around $x^*$ (the left column of Fig. 4). Based on this observation, we also initialize the acquisition optimization with a batch of inputs in $x^*$.

Note that $\alpha^*(y_D, B)$ is the information gain about $x^*$ through observing $y_B$. Thus, it is comparable between batches of different sizes. As illustrated in Appendix F, the size of $x^*$ should be at least the batch size to make the most out of the observations $y_B$. Besides, we can select the batch size adaptively at each BO iteration based on a trade-off between the increase in the information gain and the cost of an observation.

## 5 EXPERIMENTS

Several existing acquisition functions and TES are evaluated empirically on synthetic functions and real-world optimization problems. We first show the competitive performance of TES on simple synthetic functions in Sections 5.1 and 5.2. Subsequently in Section 5.3 we demonstrate that it can keep up the good performance in high-dimensional complex real-world problems.

The predictive performance of BO algorithms is measured by the immediate regret (IR), which is defined as $f^* - f(\bar{x})$ where $\bar{x}$ is the maximizer of the posterior mean given $y_D$, and $f^*$ is the true global maximum of the objective function. To account for the randomness in the optimization and the sampling of noisy observations, experiments are repeated over several random runs. The natural logarithm of the average of IR over these random runs is reported. The box plots of IR are shown in Appendix H. All experiments are initialized with a training set of 2 data samples unless otherwise specified. These synthetic and the real-world functions are
each modeled as a sample of a GP whose kernel hyperparameters are learned using maximum likelihood estimation [Rasmussen and Williams 2006]. Adam [Kingma and Ba 2015] is used to optimize TES with 300 iterations. At each stochastic iteration of Adam, 1000 samples of $y_k$ (or $y_B$) are drawn. The experiments are performed on an Intel Xeon E5-2683 v4 CPU and an NVIDIA GTX 1080 GPU.

5.1 BATCH BO WITH $|B| = 1$

We first consider BO algorithms that select 1 input query in each BO iteration. We compare $\text{TES}_{ep}$ and $\text{TES}_{sp}$ with existing algorithms: EI [Mockus et al. 1978], UCB [Srinivas et al. 2010], MES [Wang and Jegelka 2017], and PES [Hernández-Lobato et al. 2014]. There are 5 inputs in $\mathcal{X}$.

In the first experiment, we draw a function sample from a GP defined in $[0, 10]^2$ with hyperparameters $\sigma^2_x = 2$, $l_1 = l_2 = 1$, which is named the GP sampled function. The noise variance to generate observations is $\sigma^2_n = 10^{-4}$. The average results over 10 random runs are shown in Fig. [5]: $\text{TES}_{sp}$ and $\text{TES}_{ep}$ outperform other acquisition functions by converging to a better global maximum. Surprisingly, $\text{TES}_{sp}$ converges faster than $\text{TES}_{ep}$. It could be because it exploits more than $\text{TES}_{sp}$ as mentioned above (illustrated in Appendix E). The performance of PES closely matches those of $\text{TES}$ acquisition functions, while it takes longer for UCB and EI to converge. MES does not perform as well as other acquisition functions that concentrate on the information gain of the maximizers (TES and PES). Experimental results on Branin and Hartmann-3D [Lizotte 2008] are in Appendix F.

The log10P is a function that models the phosphorus field of Broom’s Barn farm [Webster and Oliver 2007] spatially distributed over a 1200m by 680m region discretized into a $31 \times 18$ grid of sampling locations. The logitomp to the base 10 values of the amount of phosphorus are recorded. Fig. [5] shows the average results over 5 random runs for the log10P with the input rescaled to $[0, 1]^2$. To generate a continuous function from the dataset, we fit a GP on the dataset. This results in a GP posterior with the dataset as training data. The hyperparameters are $\sigma^2_x = 7.669 \times 10^{-2}$, $l_1 = 9.106 \times 10^{-2}$, $l_2 = 3.971 \times 10^{-2}$, and $\sigma^2_n = 2.511 \times 10^{-2}$. The posterior mean of this GP is taken as the objective function to optimize. Note that the noise variance in this experiment is larger than that of the previous experiments. Hence, it is advantageous for information-based acquisition functions such as TES and PES as they tend to explore more than the others. Fig. [5] shows that $\text{TES}_{sp}$ converges to a maximum faster than others.

5.2 BATCH BO WITH $|B| > 1$

In this section, we consider BO of batch size larger than 1. We compare our algorithms with QEI-CL [Ginsbourger et al. 2010, BUCB [Desautels et al. 2014], QEI [Marmin et al. 2015], and LP-EI, which is the BBO-LP [González et al. 2016] by plugging in EI.

Figs. 6a-c shows BO results with $|B| = 3$ over 3 random experiments for the GP sampled function, Hartmann-4D, and log10P. The size of $\mathcal{X}^*$ is set to 5. Overall, both $\text{TES}_{sp}$ and $\text{TES}_{ep}$ achieve good performance by converging to good maxima. The difference in the performance can be explained by the fact that TES can exploit the maximizer samples from the GP posterior to quickly explore the function domain.

To illustrate the scalability of $\text{TES}_{sp}$, we experiment with large batch sizes: $|B| = 10, 20$ and 30 for the GP sampled function, and $|B| = 10, 20$ and 40 for the log10P in Figs. 6d-i. The size of $\mathcal{X}^*$ is set to be the same as that of $\mathcal{B}$. It is to make the most of the information in the batch as explained in Appendix G. In the GP sampled function experiments (Figs. 6a-f), though other acquisition functions converge faster than $\text{TES}_{sp}$, they seem to be stuck in suboptimal maxima except for LP-EI in Fig. 6i. At the initial iterations with little observations, $\mathcal{X}^*$ is likely to scatter over the whole input space, so $\text{TES}_{sp}$ explores more than other acquisition functions. At the latter iterations with a sufficient number of observations, TES can exploit to discover a good maximum. In the log10P experiments with noisier observations (Figs. 6g-i), we observe that only QEI shows similar performance to our $\text{TES}_{sp}$, though our $\text{TES}_{sp}$ outperforms for batch sizes of 20 and 40. It could be because both QEI and $\text{TES}_{sp}$ jointly optimize the batch, which is an advantage compared with other greedy batch acquisition functions in these experiments. Another observation for $\text{TES}_{sp}$ in Figs. 6d-i is that increasing the batch size improves the efficiency of BO with respect to the number of iterations.

5.3 OPTIMIZING COMPLEX REAL-WORLD PROBLEMS

In this section, we aim to illustrate that TES works well in real life. We apply our more scalable TES algorithm to two real-world scenarios that can be regarded as black-box optimization problems. Other batch BO acquisition functions mentioned previously are evaluated as comparisons.
The first real-world experiment is motivated by the computationally expensive procedure of neural architecture search in convolutional neural networks (CNNs). We train a 2-layer CNN on the CIFAR-10 dataset and aim to efficiently search for the best combination of 7 hyperparameters: batch size, number of convolutional filters, number of dense units, dropout rate, L2 regularizer, learning rate, and learning rate decay. The bounds are $[16, 512], [6, 256], [128, 2048], [0, 0.75], [10^{-7}, 10^{-3}], [10^{-7}, 10^{-1}], [10^{-7}, 10^{-3}]$ respectively and the first three hyperparameters are integers. The IR is calculated by 1 minus the test accuracy.

Fig. 7a shows BO results with $|B| = 20$ over 5 random experiments for CIFAR-10. The initial training set consists of 10 data samples. We observe greater fluctuations in the regret for all methods because the outputs of complex problems generally contain larger noises than those of synthetic functions. Overall, $\text{TES}_{ep}$ still converges the fastest to the lowest regret. All other methods except QEI-CL are stuck in suboptimal maxima obtained at the beginning few iterations. This empirical experiment shows that $\text{TES}_{ep}$ can explore multi-dimensional search spaces well in real life and find the best maximum among all the methods tested.

In our experiments, we use the Python $\text{face_recognition}$ library [Geitgey, 2017] as the target black-box FRS and alter 8 parameters linked to facial features such as facial hair (e.g., beard, mustache), marks (e.g., forehead scar, cheek scar, mole), eyeglasses (e.g., squared, round) and expressions (e.g., smile). Note that bounds are imposed on the facial feature parameters to ensure more realistic appearances of the synthesized faces, i.e., ‘physically realizable’ faces. The multimodal discriminant analysis (MMDA) face synthesizer model described by Sim and Zhang [2015] is used. The library outputs a 128-dimensional face encoding for each input face image and considers two faces as a pair of ‘match’ if the Euclidean distance between the two encodings is lower than a threshold $\theta = 0.5$. Given a gallery of 41 face images selected from the CMU Multi-PIE dataset [Gross et al., 2010] which consists of 36 males and 5 females, our objective is to modify an attacker’s face in Fig. 8a so that its distance to a registered face in the gallery is minimized. We hope the distance to go below $\theta$ for a successful break-in attack.

Fig. 7b shows BO results with $|B| = 20$ over 5 random experiments for the face attack function. The initial training size is again 10. Similar to what we observed in the CIFAR-10 experiment, $\text{TES}_{ep}$ achieves the lowest regret while other methods only obtain suboptimal maxima. $\text{TES}_{ep}$ explores over the whole input space for about 10 iterations (or 200 samples) before turning to exploitation to discover a good maximum. Similar behavior is seen in Fig. 6. Additionally, the box plots of IR are included in Appendix H.

We show the visualization of a typical result after iterations of optimization using BO with our $\text{TES}_{ep}$ acquisition func-
Figure 8: Visualization of a typical result. (a) is the original image of the attacker. (b) shows the synthesized image of the attacker. (c) is the ‘matched’ image in the gallery.

In this particular case, the attacker’s face is modified to Fig. 8b such that the distance to a registered face encoding in the gallery is optimized to 0.4534, implying that the privacy and security of the FRS have been compromised since the distance is smaller than the threshold $\theta = 0.5$. Notably, the modified face is ‘physically realizable’, i.e., the attacker could grow a beard, change the glasses, put some scars makeup and smile to fool the FRS. The victim’s face is shown in Fig. 8c. Therefore, our proposed algorithm is effective in such real-world optimization problems.

6 CONCLUSION

This paper presents trusted-maximizers entropy search (TES) for performing Bayesian optimization and its batch variant. Both stochastic approximation with sampling and deterministic approximation with a Gaussian distribution are investigated, which results in TES$_{sp}$ and TES$_{ep}$, respectively. While TES$_{sp}$ produces a better approximation of the posterior belief, TES$_{ep}$ is less expensive to evaluate. Therefore, TES$_{sp}$ can be scaled to BO with large batch sizes. TES$_{sp}$ and TES$_{ep}$ achieve favorable performance compared with existing acquisition functions in experiments with synthetic benchmark objective functions and complex real-world optimization problems.

A EVALUATION OF \( p(x^*|y_D) \)

The probability \( p(x^*|y_D) \) can be expressed as:
\[
p(x^*|y_D) = p(f(x^*) \geq f(x)) \forall x \in X^*|y_D)
= p(J_{X^*}f_{X^*} \leq 0|y_D)
\]
where \( J_{X^*} \) is a matrix of size \( |X^*| \times |X^*| \) with 0 entries except for \( J_{ii} = 1 \), \( J_{ij} = -1 \) if \( i \neq j \) where \( j \) is the index of \( x^* \) in \( X^* \). As \( p(f_{X^*}|y_D) \) is the p.d.f. of a multivariate Gaussian \([1] \), so is \( p(J_{X^*}f_{X^*}|y_D) \). Hence, \( p(J_{X^*}f_{X^*} \leq 0|y_D) \) can be computed efficiently.

B IMPORTANCE SAMPLING FROM \( p(f_{X^*}|y_D, x^*) \)

Let \( f_{x^*} \triangleq (f(x^*))_{x^* \in X^* \setminus \{x^*\}} \) denote the function values at \( X^* \setminus \{x^*\} \). We have \( p(f_{X^*}|y_D, x^*) \propto p(f_{X^*}, x^*|y_D) \) which equals
\[
p(x^*|f_{x^*}, y_D)p(f_{x^*}|y_D)p(f(x^*)|x^*, f_{x^*}, y_D).
\]
We can first draw samples of \( f_{x^*} \) from the p.d.f. \( p(f_{x^*}|y_D) \), then weight these samples with \( p(x^*|f_{x^*}, y_D) \). Sampling from \( p(f_{x^*}|y_D)p(f(x^*)|x^*, f_{x^*}, y_D) \) is a 2-step process:

1. Drawing a sample of \( f_{x^*} \) from \( p(f_{x^*}|y_D) \) which is the p.d.f. of a multivariate Gaussian distribution.
2. Given a sample of \( f_{x^*} \), drawing a sample of \( f(x^*) \) from \( p(f(x^*)|x^*, f_{x^*}, y_D) \) which is a lower-truncated Gaussian distribution (truncation of lower tail at \( f^+ \triangleq \max_{x^* \in X^* \setminus \{x^*\}} f(x^*) \)).

The weight of a sample \( f_{X^*} \) is \( p(x^*|f_{x^*}, y_D) \) which can be computed efficiently.
\[
p(x^*|f_{x^*}, y_D)
= \int p(x^*, f(x^*)|f_{x^*}, y_D) \, df(x^*)
= \int p(x^*|f_{X^*}, y_D)p(f(x^*)|f_{X^*}, y_D) \, df(x^*)
= \int I_{f(x^*) \geq f^+} p(f(x^*)|f_{X^*}, y_D) \, df(x^*)
= 1 - \Phi_{p(f(x^*)|f_{X^*}, y_D)}(f^+)
\]
where \( \Phi_{p(f(x^*)|f_{X^*}, y_D)}(f^+) \) is the c.d.f. of the GP predictive belief \( p(f(x^*)|f_{X^*}, y_D) \) evaluated at \( f^+ \), and \( I_{f(x^*) \geq f^+} \) is an indicator function such that it is 1 if \( f(x^*) \geq f^+ \) and 0 otherwise.

C CLOSED-FORM EXPRESSION OF \( p(y_{y_D}|f_{X^*}, Y_D) \)

At a BO iteration, let \( z \triangleq [f_X; y_D] \) be a column vector where the first \( |X^*| \) elements are \( f_{X^*} \) and the last \( |D| \) elements are observations \( y_D \). Let \( t \) be a column vector where the first \( |X^*| \) inputs are \( X^* \) and the last \( |D| \) inputs are observed inputs \( D \). We have the expression:
\[
p(y_{y_D}|f_{X^*}, Y_D) = \mathcal{N}(y_{y_D}; \mu_{y_D}, \sigma_{y_D}^2)
\]
where \( \mathcal{N} \) is a Gaussian p.d.f., \( \mu_{y_D} \) and \( \sigma_{y_D}^2 \) are the mean and standard deviation of \( p(f(x^*)|f_{X^*}, y_D) \), which are used in Section E.

D EXPECTATION PROPAGATION APPROXIMATION FOR \( p(f_{X^*}|y_D, x^*) \)

To approximate \( p(f_{X^*}|y_D, x^*) \), it is expressed as
\[
p(f_{X^*}|y_D, x^*) \propto p(f_{X^*}|y_D)p(x^*|f_{X^*}, y_D)
\]
\[
= p(f_{X^*}|y_D) \prod_{x^* \in X^* \setminus \{x^*\}} I_{f(x^*) \geq f(x^*)}
= p(f_{X^*}|y_D) \prod_{x^* \in X^* \setminus \{x^*\}} I_{x^* \neq x^*} f_{x^*} \geq 0
\]
where \( c_{x^*} \) is a column vector of length \( |X^*| \) with 0 entries except for the \( i \)-th entry of value \( -1 \), the \( j \)-th entry of value \( 1 \) where \( i \) and \( j \) are the indices of \( x^* \) and \( x^* \) in \( X^* \), respectively; \( I \) is the indicator function.

The p.d.f. \( p(f_{X^*}|y_D, x^*) \) is approximated with a Gaussian distribution by EP, i.e., \( p(f_{X^*}|y_D, x^*) \approx \mathcal{N}(f_{X^*}; \mu_{\text{ep}}, \Sigma_{\text{ep}}) \triangleq q_{\text{ep}}(f_{X^*}|y_D, x^*) \). As in PPES [Shah and Ghahramani2015], to construct this Gaussian approximation, each indicator term (involved \( I \)) is approximated with a univariate scaled Gaussian p.d.f.:
\[
q_{\text{ep}}(f_{X^*}|y_D, x^*) \approx \mathcal{N}(f_{X^*}; \mu_{\text{ep}}, \Sigma_{\text{ep}})
\]
where \( \mathcal{N}(f_{X^*}; \mu, K) \) denotes the GP predictive belief of \( f_{X^*} \) given \( y_D \), the scale factor \( \tilde{Z}_{x^*} \) and the variance \( \tilde{r}_{x^*} \) are positive, \( \mu_{x^*} \in \mathbb{R} \). The parameters \( \{\tilde{Z}_{x^*}, \mu_{x^*}, \tilde{r}_{x^*}\}_{x^* \in X^* \setminus \{x^*\}} \) are called the site parameters, which are optimized such that the Kullback-Leibler divergence of \( q_{\text{ep}}(f_{X^*}|y_D, x^*) \) from \( p(f_{X^*}|y_D, x^*) \) is minimized, i.e., their means and covariance matrices match. As \( \{\tilde{Z}_{x^*}, \mu_{x^*}, \tilde{r}_{x^*}\}_{x^* \in X^* \setminus \{x^*\}} \) are independent from \( f_{X^*} \), we only optimize \( \{\mu_{x^*}, \tilde{r}_{x^*}\}_{x^* \in X^* \setminus \{x^*\}} \).

As the product of Gaussian p.d.f. leads to a Gaussian p.d.f.,
we have

$$\Sigma_{ep} = \left( \hat{K}^{-1} + \sum_{x' \in \mathcal{X}' \setminus \{x'\}} \frac{1}{x'} c_{x'} c_{x'}^\top \right)^{-1}$$ (11)

$$\mu_{ep} = \Sigma_{ep} \left( \hat{K}^{-1} \bar{m} + \sum_{x' \in \mathcal{X}' \setminus \{x'\}} \bar{\mu}_{x'} \hat{c}_{x'} \right).$$ (12)

To update the site parameters, we first compute the cavity distributions

$$p_{\setminus x'}(f_{x'}) \triangleq \frac{q_{\text{EP}}(f_{x'}|y_{\mathcal{D}}, x^*)}{Z_{\setminus x'} \mathcal{N}(c_{x'}^\top f_{x'}; \bar{\mu}_{x'}, \bar{\tau}_{x'})}.$$ (13)

Note that in the next step, we would like to approximate the distribution of $c_{x'}^\top f_{x'}$, so we only require the cavity distribution of the r.v. $c_{x'}^\top f_{x'}$, which is denoted as:

$$p_{\setminus x'}(c_{x'}^\top f_{x'}) \triangleq \frac{\tilde{p}(c_{x'}^\top f_{x'})}{Z_{\setminus x'} \mathcal{N}(c_{x'}^\top f_{x'}; \bar{\mu}_{x'}, \bar{\tau}_{x'})}.$$ (14)

where $\tilde{p}(c_{x'}^\top f_{x'}) = \mathcal{N}(c_{x'}^\top f_{x'}; \bar{\mu}_{x'}, \bar{\tau}_{x'})$. Let the Gaussian mean and variance of $p_{\setminus x'}(c_{x'}^\top f_{x'})$ are $\mu_{\setminus x'}$ and $\tau_{\setminus x'}$, respectively, we have

$$\mu_{\setminus x'} = \left( (c_{x'}^\top \Sigma_{ep} c_{x'})^{-1} - \bar{\tau}_{x'}^{-1} \right)^{-1} \left( c_{x'}^\top \Sigma_{ep} \bar{m} ight)$$

$$\tau_{\setminus x'} = \tau_{x'} \left( (c_{x'}^\top \Sigma_{ep} c_{x'})^{-1} - \bar{\mu}_{x'} \right).$$

Next, the projection step of EP is to do moment matching of $Z_{\setminus x'} \mathcal{N}(c_{x'}^\top f_{x'}; \bar{\mu}_{x'}, \bar{\tau}_{x'}) p_{\setminus x'}(c_{x'}^\top f_{x'})$ with $\mathbf{I}_{c_{x'}^\top f_{x'}, \geq 0} p_{\setminus x'}(c_{x'}^\top f_{x'})$. We use the derivatives of the zeroth moment to compute moments of $\mathbf{I}_{c_{x'}^\top f_{x'}, \geq 0} p_{\setminus x'}(c_{x'}^\top f_{x'})$, denoted as $\hat{\mu}_{x'}$ (mean) and $\hat{\tau}_{x'}$ (variance). The zeroth moment is computed as:

$$\hat{Z}_{x'} \triangleq \int \mathbf{I}_{c_{x'}^\top f_{x'}, \geq 0} p_{\setminus x'}(c_{x'}^\top f_{x'}) \, d (c_{x'}^\top f_{x'})$$

$$= \int \mathbf{I}_{c_{x'}^\top f_{x'}, \geq 0} \mathcal{N}(c_{x'}^\top f_{x'}; \mu_{x'}, \tau_{x'}) \, d (c_{x'}^\top f_{x'})$$

$$= \Phi(\beta_{x'})$$

where $\phi$ and $\Phi$ are the p.d.f. and c.d.f. of the standard Gaussian distribution, respectively. On the other hand, we can express the derivatives of $\hat{Z}_{x'}$ as:

$$\frac{\partial \hat{Z}_{x'}}{\partial \mu_{x'}} = \frac{\phi(\beta_{x'})}{\sqrt{\tau_{x'}}}$$

$$\frac{\partial \hat{Z}_{x'}}{\partial \tau_{x'}} = -\frac{1}{2} \frac{\mu_{x'}}{\sqrt{\tau_{x'}}} \phi(\beta_{x'})$$

(13)

(14)

Finally, we update the parameters $\mu_{ep}$ and $\Sigma_{ep}$ by (11) and (12). The process is repeated for all $x' \in \mathcal{X}' \setminus \{x^*\}$ until convergence.
E  

CLOSED-FORM EXPRESSION OF 
\[ p(f(x)|y_D, x^*) \]

We can express the predictive posterior distribution \( p(f(x)|y_D, x^*) \) as:

\[
p(f(x)|y_D, x^*) = \int p(f(x)|f_{x^*}, y_D, x^*)p(f_{x^*}|y_D, x^*) \, df_{x^*}.
\]

\[
= \int p(f(x)|f_{x^*}, y_D)p(f_{x^*}|y_D, x^*) \, df_{x^*}.
\]

\[
\approx \int p(f(x)|f_{x^*}, y_D)q_{ep}(f_{x^*}|y_D, x^*) \, df_{x^*}.
\]

\[
= \mathcal{N}(f(x); \mu_{x^*}^+, \sigma_{2|x^*}^2)\mathcal{N}(f_{x^*}; \mu_{ep}, \Sigma_{ep}) \, df_{x^*}.
\]

where \( p(f(x)|f_{x^*}, y_D) \) \( \equiv \mathcal{N}(f(x); \mu_{x^*}^+, \sigma_{2|x^*}^2) \) \( \mu_{x^*}^+ \) and \( \sigma_{2|x^*}^2 \) are defined in Eq. 9 and Eq. 10, respectively.

Let \( \tilde{r} \triangleq K_{xx}^{-1}k_{xx}, \tilde{a} \triangleq r_{x^*}, \) and \( b \triangleq \tilde{r}_{D}y_D \) where \( r_{x^*} \) and \( r_{D} \) are the first \(|X^*|\) and the last \(|D|\) elements of the column vector \( r \). Then, we have

\[
\mu_{x^*}^+ = a^Tf_{x^*} + b
\]

\[
p(f(x)|y_D, x^*) \approx \int \mathcal{N}(f(x); a^Tf_{x^*} + b, \sigma_{2|x^*}^2) \times \mathcal{N}(f_{x^*}; \mu_{ep}, \Sigma_{ep}) \, df_{x^*}.
\]

\[
= \mathcal{N}(f(x); a^T\mu_{ep} + b, \sigma_{2|x^*}^2 + a^T\Sigma_{ep}a) .
\]

Hence,

\[
p(y_{x^*}|y_D, x^*) \approx \mathcal{N}(f(x); a^T\mu_{ep} + b, \sigma_{2|x^*}^2 + a^T\Sigma_{ep}a + \sigma_n^2) \]

\( \triangleq q_{ep}(y_{x^*}|y_D, x^*) .\)

F  

AN EXAMPLE ON EXPLOITATION VS. EXPLORATION OF DIFFERENT TES APPROXIMATION METHODS

Fig. 9 shows an example where TES_{sp} and TES_{ep} select different inputs. In particular, TES_{ep} selects an input where the GP posterior mean of its function value is higher than that of the input TES_{sp} selects. Scrutinizing more carefully on the acquisition function values \( f(0) \) and \( f(2) \), we observe that the difference in values of TES_{sp} is smaller than that of TES_{ep}. In these cases, it means that TES_{ep} has a stronger preference to a larger mean function value than TES_{sp}. Hence, it is observed in these cases that TES_{ep} exploits more than TES_{sp}.

G  

TES_{EP} OF DIFFERENT BATCH SIZES

Note that \( \alpha^*(y_D, B) \) is the information gain about \( x^* \) through observing \( y_B \). Thus, it is comparable between batches of different sizes. Given the size of \( x^* \) as 5, Fig. 10 shows the maximum TES_{ep} value (i.e., maximum information gain) for different batch sizes. We observe that increasing the batch size to be larger than \(|X^*|\) only yields an insignificant amount of TES_{ep}. Therefore, the size of \( x^* \) should be at least the batch size to make the most out of the observations \( y_B \). Besides, we can select the batch size adaptively at each BO iteration based on a trade-off between the increase in the information gain and the cost of an observation.

H  

ADDITIONAL EXPERIMENT RESULTS

Fig. 11 shows the average of the results over 10 random runs for 2 synthetic functions: Branin defined in \([0, 1]^2\), and Hartmann-3D defined in \([0, 1]^3\) [Lizotte 2008]. As our optimization problem is maximization and these synthetic functions are often minimized, we take the negative values of these functions as objective functions. In these experiments, the noise variance is fixed to \( \sigma_n^2 = 10^{-4} \). Note that unlike the synthetic function we sample from a GP posterior, the assumption of using an isotropic SE kernel might be

\(^2\text{A kernel } k_{xx'} \text{ is isotropic if it depends on } |x - x'| \text{ only.}\)
violated in these synthetic functions. However, the empirical results in Fig. 11 still show a reasonable performance. Overall, TES acquisition functions outperform others, but the difference is less obvious in the Branin function. It could be because Branin is a simple function to optimize (i.e., having 3 local maxima in a 2-dimensional input space). In the Hartmann-3D experiment, EI outperforms PES, which could be because PES explores more than EI as explained by Hernández-Lobato et al. [2014].

Additionally, the box plots of IR in the last iteration of random experimental runs are shown in Figs. 12, 13, and 14.
