ABSTRACT

In this paper, we extend the recently developed reduced collocation method [3] to the nonlinear case, and propose two analytical preconditioning strategies. One is parameter independent and easy to implement, the other one has the traditional affinity with respect to the parameters, which allows an efficient implementation through an offline-online decomposition. Overall, preconditioning improves the quality of the error estimation uniformly on the parameter domain, and speeds up the convergence of the reduced solution to the truth approximation.

RÉSUMÉ

On étend dans cette note la méthode de collocation réduite récemment introduite dans [3] au cas non linéaire et on propose deux stratégies de préconditionnement dont une est indépendante des paramètres et facile à mettre en œuvre et l’autre possède la propriété classique de décomposition affine en les paramètres qui permet une mise en œuvre rapide en ligne/hors ligne. Ces stratégies améliorent la qualité de l’approximation et la vitesse de convergence.

Version française abrégée

La méthode de base réduite classique (RBM) [2,6–8] pour l’approximation de la solution d’équations aux dérivées partielles (EDP) paramétrées du type \( \frac{d}{dx}[L(\mu)u(x)](x) = f(x; \mu), x \in \mathbb{R} \subseteq \mathbb{R}^n \) repose sur la définition d’un espace de discrétisation...
ad hoc, engendré par des solutions particulières de l’EDP en certains paramètres bien choisis. Ces solutions particulières doivent être préalablement approchées par une méthode traditionnelle spectrale ou d’éléments finis, par exemple. Elle est principalement développée dans le cadre variationnel et permet la résolution en des temps bien plus faible que des méthodes traditionnelles. Dans certains cadres, néanmoins, l’approche de collocation préférable à l’approche variationnelle, en particulier lorsque la physique est complexe. La méthode de collocation réduite récemment introduite dans [3] permet de poser le problème de cette façon. Ainsi, lorsque la méthode traditionnelle est de type spectral collocation où, après avoir défini un opérateur discret \( L_{\mathcal{N}}(\mu) \), on cherche un polynôme \( u_{\mathcal{N}}^N(x_j) = f(x_j; \mu) \) est vérifié exactement sur un ensemble de \( N \) points de collocation \( \mathcal{N} = \{x_j\}_{j=1}^N \), l’approche de collocation réduite propose une approximation \( u_{\mu}^{(N)} : u_{\mu}^{(N)} = \sum_{j=1}^N c_j(\mu) u_{\mu}^N \) vérifiant (1), soit au sens des moindre carrés (LSRCM), puisqu’il y a plus de point \( x_k \) que de coefficients \( c_j \) (en effet \( N \ll \mathcal{N} \)), soit seulement en certains points bien choisis \( x \in C_\mathcal{R}^\mu \) (ERCM).

Les méthodes de collocation sont connues pour être moins stables que les méthodes variationnelles. Pour rectifier cet inconvénient, nous proposons deux types de préconditionnements analytiques, basés sur la définition d’un opérateur de préconditionnement \( P \) et sur une approche de \( P L_{\mathcal{N}}(\mu) u_{\mu}^N \) tel que \( [L_{\mathcal{N}}(\mu)u_{\mu}^N](x_j) = f(x_j; \mu) \) est vérifié exactement sur un ensemble de \( N \) points de collocation \( \mathcal{N} = \{x_j\}_{j=1}^N \), l’approche de collocation réduite propose une approximation \( u_{\mu}^{(N)} : u_{\mu}^{(N)} = \sum_{j=1}^N c_j(\mu) u_{\mu}^N \) vérifiant (1), soit au sens des moindre carrés (LSRCM), puisqu’il y a plus de point \( x_k \) que de coefficients \( c_j \) (en effet \( N \ll \mathcal{N} \)), soit seulement en certains points bien choisis \( x \in C_\mathcal{R}^\mu \) (ERCM).

Les méthodes de collocation sont connues pour être moins stables que les méthodes variationnelles. Pour rectifier cet inconvénient, nous proposons deux types de préconditionnements analytiques, basés sur la définition d’un opérateur de préconditionnement \( P \) et sur une approche de \( P L_{\mathcal{N}}(\mu) u_{\mu}^N \) tel que \( [L_{\mathcal{N}}(\mu)u_{\mu}^N](x_j) = f(x_j; \mu) \) est vérifié exactement sur un ensemble de \( N \) points de collocation \( \mathcal{N} = \{x_j\}_{j=1}^N \), l’approche de collocation réduite propose une approximation \( u_{\mu}^{(N)} : u_{\mu}^{(N)} = \sum_{j=1}^N c_j(\mu) u_{\mu}^N \) vérifiant (1), soit au sens des moindre carrés (LSRCM), puisqu’il y a plus de point \( x_k \) que de coefficients \( c_j \) (en effet \( N \ll \mathcal{N} \)), soit seulement en certains points bien choisis \( x \in C_\mathcal{R}^\mu \) (ERCM).

Les méthodes de collocation sont connues pour être moins stables que les méthodes variationnelles. Pour rectifier cet inconvénient, nous proposons deux types de préconditionnements analytiques, basés sur la définition d’un opérateur de préconditionnement \( P \) et sur une approche de \( P L_{\mathcal{N}}(\mu) u_{\mu}^N \) tel que \( [L_{\mathcal{N}}(\mu)u_{\mu}^N](x_j) = f(x_j; \mu) \) est vérifié exactement sur un ensemble de \( N \) points de collocation \( \mathcal{N} = \{x_j\}_{j=1}^N \), l’approche de collocation réduite propose une approximation \( u_{\mu}^{(N)} : u_{\mu}^{(N)} = \sum_{j=1}^N c_j(\mu) u_{\mu}^N \) vérifiant (1), soit au sens des moindre carrés (LSRCM), puisqu’il y a plus de point \( x_k \) que de coefficients \( c_j \) (en effet \( N \ll \mathcal{N} \)), soit seulement en certains points bien choisis \( x \in C_\mathcal{R}^\mu \) (ERCM).

1. Introduction

The Reduced Basis Method (RBM) [2,6–8] has been developed to numerically solve PDEs in scenarios that require a large number of numerical solutions to a parameterized PDE, and in which we are ready to expend significant computational time to pre-compute data that can be later used to compute accurate solutions in real time. The RBM splits the solution procedure into two parts: an offline part where a greedy algorithm is utilized to judiciously select \( N \) parameter values for pre-computation, and an online part where the solution for many new parameters is efficiently approximated by a Galerkin projection onto the low-dimensional space spanned by these \( N \) pre-computed solutions.

While Galerkin methods (that are mostly used for RBM) are derived by requiring that the projection of the residual onto a prescribed space is zero, collocation methods require the residual to be zero at some pre-determined collocation points. They are attractive for their ease of implementation, particularly for time-dependent nonlinear problems [4,9]. In [3], two of the authors developed the so-called Reduced Collocation Method (RCM). It adopts the RBM idea for collocation methods providing a strategy for practitioners who prefer a collocation, rather than Galerkin’s approach. Our current implementation of this method for both the truth solver and the online reduced solver, but the offline part could be based on a variational approach as well. Furthermore, one of the two approaches in [3], the empirical reduced collocation method (ERCM), allows us to eliminate a potentially costly online procedure that is needed for non-affine problems with a Galerkin approach. The method’s efficiency matches (or, for non-affine problems, exceeds) that of the traditional RBM in the Galerkin framework.

However, collocation methods may suffer from bad conditioning. In this paper, we propose and test two analytical preconditioning strategies to address this issue in the parametric setting of RCM. One strategy is parameter independent, which is advantageous for the ease of implementation. The other one is parameter dependent, but has the traditional affinity with respect to the parameters, which allows extremely efficient implementation through an offline–online decomposition. Overall, we show that the preconditioning uniformly improves the quality of the approximation, and speeds up the convergence of the solution process without adversely impacting the efficiency of the method in any significant way. While the focus and novelty of this paper is primarily the design of the analytical preconditioners, we also describe the extension of the RCM to the nonlinear case. In Section 2, we briefly review RCM and describe our analytical preconditioners. Numerical results are described in Section 3.

2. The algorithms

We begin with a linear parameterized PDE depending on a parameter \( \mu \in D \subseteq \mathbb{R}^d \), written in a strong form as \( [L(\mu)u(\mu)](x) = f(x; \mu), x \in \Omega \subseteq \mathbb{R}^n \) with appropriate boundary conditions. We approximate the solution to this equation using a collocation approach: for any \( \mu \in D \), we define a discrete differentiation operator \( L_{\mathcal{N}}(\mu) \), and a discrete (polynomial) solution \( u_{\mathcal{N}}^N \) such that \( [L_{\mathcal{N}}(\mu)u_{\mathcal{N}}^N](x_j) = f(x_j; \mu) \) on a given set of collocation points \( \mathcal{N} = \{x_j\}_{j=1}^N \), usually taken as
a tensor product of $N_k$ collocation points for each dimension that is allowed by rectangular domains. We assume that the resulting approximate solution $u^N_{\mu}$ is highly accurate and refer to it as the “truth approximation”.

2.1. Online algorithms

For completeness, we briefly outline the RCM [3]. The idea is that when the solution for any parameter value $\mu^* \in \mathcal{D}$ is needed, instead of solving for the costly truth approximation $u^N_{\mu^*}$, we somehow combine $N$ pre-computed truth approximations $u^N_{\mu^*}, \ldots, u^N_{\mu^*}$ to produce a surrogate solution $u^{N(N)}_{\mu^*}$: $u^{N(N)}_{\mu^*} = \sum_{j=1}^{N} c_j(\mu^*) u^{N}_j$. The key feature of the algorithm is the requirement that the surrogate solution $u^{N(N)}_{\mu^*}$ will satisfy the discretized differential equation in some sense $L_N(\mu^*) u^{N(N)}_{\mu^*} \approx f(\mu^*)$. Exploiting the linearity of the operator, we observe that the system of equations we wish to solve is: find $c(\mu^*)$ such that

$$c(\mu^*) = (c_1(\mu^*), c_2(\mu^*), \ldots, c_N(\mu^*))^T, \quad \sum_{j=1}^{N} c_j(\mu^*) [L_N(\mu^*) u^{N}_j](x_k) \approx f(x_k; \mu^*) \tag{1}$$

Satisfying the above equation exactly for $k = 1, \ldots, N$ is usually an overdetermined system since we have only $N$ unknowns, but $N \gg N$ equations.

Least squares approach. When faced with an overdetermined system, we can determine the coefficients by satisfying Eq. (1) in a least squares sense: we define, for any $\mu^*$, an $N \times N$ matrix $\lambda_N(\mu^*)$ with $j$th column $L_N(\mu^*) u^{N}_j$, and vector of length $N$, $f^N_N(\mu^*) = f(x_j; \mu^*)$, $x_j \in \mathcal{C}^N$, and solve the least squares problem $\lambda_N^T(\mu^*) \lambda_N(\mu^*) c(\mu^*) = \lambda_N^T(\mu^*) f^N_N(\mu^*)$ to obtain $c(\mu^*)$.

Reduced collocation approach. Our second approach is more natural from the collocation point of view. We determine the coefficients $c(\mu^*)$ by enforcing (1) at a reduced set of collocation points $C^N_N$. In other words, we solve $\sum_{j=1}^{N} c_j(\mu^*) [L_N(\mu^*) u^{N}_j](x) = f(x; \mu^*)$ for $x \in C^N_N$, which can also be written as $\|N_N(\mu^*) c(\mu^*) = f^N_N$, where $\|N_N$ is a $N \times N$ matrix, that extracts the $N$ values of a $N$-vector associated with the indices of the reduced set of collocation points. Later we will demonstrate how this set of points can be determined, together with the choice of basis functions, through the greedy algorithm.

2.2. Offline–online decomposition

The size of the matrix we need for solving $c(\mu^*)$ for each new $\mu^*$ is $N \times N$, but its assembly is not obviously independent of $N$. For that purpose, we need the affine assumption on the operator as in the Galerkin framework. Thus, the overall online component is independent of $N$ after a preparation stage where all the parameter independent quantities are precomputed [3]. We remark that there are remedies available when the parameter-dependence is not affine [1].

2.3. Analytical preconditioning

Collocation methods are frequently ill-conditioned. The situation is exacerbated when we form the normal equation in the Least Squares approach. In this section, we propose two analytical preconditioning techniques. One is parameter-independent and the other is parameter-dependent. Both will provide an operator $P$ such that the discretization is based on the minimization of $P L_N(\mu) u^N_{\mu}(x_j) = P f(x_j; \mu)$ and the reduced problem in, e.g., the second approach becomes

$$\sum_{j=1}^{N} c_j(\mu^*) \|N_N(\mu^*) u^{N}_j) = \|N_N(P f)$$

Parameter-independent approach: We propose using $P^{\mu^c} := L_N(\mu^c)^{-1}$ as a preconditioning operator. Here $\mu^c$ is the center of the parameter domain $\mathcal{D}$. We remark that this preconditioner is in general, ideal for $\mu = \mu^c$ (making condition number exactly 1). Moreover, it is affordable in the parametric setting, since we can perform the $N$-dependent operations for the offline preconditioning once for all.

Parameter-dependent approach: $P^{\mu}$ works well. However, it is more effective when $\mu$ is close to $\mu^c$. To have a preconditioning operator working well uniformly on the parameter domain, we need a parameter-dependent one. In addition, for the preconditioning to be meaningful in our parametric setting, a key requirement is that it satisfies an affine property similar to those for the operator $L_N(\mu)$.

---

3 Note that, in general the least squares problem should be solved using the QR factorization, but in the current context, the resulting $Q$ and $R$ matrices depend on $\mu^c$, which is problematic since the construction of these matrices is expensive and thus the online cost does not scale with a complexity depending only on $n$.

4 $L(\mu)$ can be written as a linear combination of parameter-dependent coefficients and parameter-independent operators: $L(\mu) = \sum_{q=1}^{Q} \alpha^q(\mu) L_q$. Similarly, for $f$: $f(x; \mu) = \sum_{q=1}^{Q} \alpha^q(\mu) f^q(x)$.
Assuming that our (d-dimensional) parameter domain is rectangular, we form $2^d$ operators at the vertices of the domain: $L_{\mathcal{N}}(\mu^V)$ for $i = 1, \ldots, 2^d$, find their inverses $P_{ij} = (L_{\mathcal{N}}(\mu^V))^{-1}$, and define the preconditioning operator through interpolation. In the case $d = 2$ (we assume $\mu = (\mu_1, \mu_2) \in [0, 1]^2$ without loss of generality), this is a $Q_1$ interpolation defined as below: $P(i; \mu) = P_{00}(1 - \mu_1)(1 - \mu_2) + P_{01}(1 - \mu_1)\mu_2 + P_{10}(1 - \mu_2)\mu_1 + P_{11}\mu_1\mu_2$, where $P_{ij}$ is $P_V$ with $V$ being the $(i, j)$-corner.5

2.4. Offline algorithms

In this section we describe the two greedy algorithms for the least squares and the reduced collocation approaches for choosing the reduced basis set $\{u_{\mu_1}^N, \ldots, u_{\mu_N}^N\}$. We assume that given $\{u_{\mu_1}^N, \ldots, u_{\mu_N}^N\}$ we can compute an upper bound $\Delta_l(\mu)$ for the error of the reduced solution $u_{\mu_l}^N$ for any parameter $\mu$ [3].

Algorithm 1 Least Squares Reduced Collocation Method (LSRCM): offline procedure.

1. Discretize the parameter domain $\mathcal{D}$ by $\Xi$, and denote the center of $\mathcal{D}$ by $\mu^c$.
2. Randomly select $\mu_1$, solve $L_{\mathcal{N}}(\mu)u_{\mu_1}^N(x) = f(x; \mu_1)$ for $x \in \mathcal{N}$ and let $\xi_1^N = u_{\mu_1}^N$.
3. For $i = 2, \ldots, N$ do
   i) for all $\mu \in \Xi$, form $A_{i-1}(\mu) = (L_{\mathcal{N}}(\mu)\xi_{i-1}^N, L_{\mathcal{N}}(\mu)\xi_{i-1}^N, \ldots, L_{\mathcal{N}}(\mu)\xi_{i-1}^N)$.
   ii) for all $\mu \in \Xi$, solve $A_{i-1}(\mu)\xi_i = c_{i-1}(\mu)$ to obtain $u_{\mu_i}^{l-1} = \sum_{j=1}^{i-1} c_{i-1}j^N$ and $\Delta_{i-1}(\mu)$.
   iii) set $\mu_i = \arg\max_{\mu \in \Xi} A_{i-1}(\mu)$ and solve $L_{\mathcal{N}}(\mu_i)u_{\mu_i}^N(x) = f(x; \mu_i)$ for $x \in \mathcal{N}$.
   iv) apply a modified Gram–Schmidt transformation, with an inner product defined by $(u, v) = L_{\mathcal{N}}(\mu_i)u, L_{\mathcal{N}}(\mu_i)v)(\mu_i)$, on $\{\xi_1^N, \xi_2^N, \ldots, \xi_i^N, u_{\mu_i}^N\}$ to obtain $\{\xi_1^N, \xi_2^N, \ldots, \xi_i^N\}$.

Algorithm 2 Empirical Reduced Collocation Method (ERCM): offline procedure.

1. Randomly select $\mu$, solve $L_{\mathcal{N}}(\mu)u_{\mu}^N(x) = f(x; \mu)$, let $x_1^N = \arg\max_{x \in \Xi} |u_{\mu}^N(x)|$, $\xi_1^N = u_{\mu}^N\left|_{x_1^N}\right.$.
2. For $i = 2, \ldots, N$ do
   i) Let $x_i^N = (x_i, \ldots, x_{i-1})$.
   ii) for all $\mu \in \Xi$, solve $\sum_{j=1}^{i-1} c_{i-1}j^N L_{\mathcal{N}}(\mu)u_{\mu_j}^N(x) = f(x; \mu)$ for $x \in \mathcal{N}^{i-1}$ to obtain $u_{\mu_i}^{l-1} = \sum_{j=1}^{i-1} c_{i-1}j^N$.
   iii) Set $\mu_i = \arg\max_{\mu \in \Xi} A_{i-1}(\mu)$ and solve $L_{\mathcal{N}}(\mu_i)u_{\mu_i}^N(x) = f(x; \mu_i)$.
   iv) Find $\alpha_1, \ldots, \alpha_{i-1}$ such that, if we define $\xi_i^N = u_{\mu_i}^N - \sum_{j=1}^{i-1} \alpha_j \xi_j^N$, we have $\xi_i^N(x) = 0$ for $j = 1, \ldots, i-1$.
   v) Set $x_i^N = \arg\max_{x \in \Xi} |\xi_i^N|$ and $\xi_i^N = \xi_i^N\left|_{x_i^N}\right.$
   vi) Apply a modified Gram–Schmidt transformation on $\{\xi_1^N, \ldots, \xi_i^N\}$.

2.5. Extension to the nonlinear case

The ERCM approach is more economical than the EIM implementation of the variational RB for linear problems having a large number of varying coefficients, such as the case when geometry is a parameter [5]. Here, we outline the procedure when we have a general nonlinear operator $G(u; \mu) + L(\mu)u$ where $G(u; \mu)$ is nonlinear. The parameter dependence can be handled in the same way with possibly the Empirical Interpolation [1] needed, so it suffices to assume $G(u; \mu) \equiv G(u)$. In the following, we present our approach through the example of the viscous Burgers’ equation $u_{tt} - \mu u_{xx} = f(t)$; the formal extension to multi-dimension vector equations is straightforward. In the case of Burgers’ equation, the discretized system for any parameter $\mu$ becomes $u \mathbf{D}_u - \mu \mathbf{D}_u \mathbf{D}_u = f_{\mu}$, where $u$ is the $N \times 1$ vector containing the point values of $u$ on the Chebyshev grid, $\mathbf{D}_u$ is the well-known Hadamard product for vectors that denotes element-wise multiplication, and $\mathbf{D}_u$ and $\mathbf{D}_u$ are the $N \times N$ and second order differentiation matrices, respectively. We assume that we are given $N$ solutions $u_{\mu}^N_{\mu}$ and we define $u_{\mu}^{(N)} = \sum_{j=1}^{N} c_j(\mu^*)u_{\mu}^N_{\mu}$. We find the values of the unknown coefficients $c_j$ by satisfying a nonlinear equation of the form $G(c) - \mu c L(c) = f_{\mu}$. Here, $c$ is the column vector of coefficients $c_j$ of length $N$, $L$ is an $N \times N$ matrix, and $G : \mathbb{R}^{N \times 1} \to \mathbb{R}^{N \times 1}$ is a nonlinear function. These solutions are then solved by some iterative fixed-point-like method. For the ERCM case, $L$ and $G$ come from the discrete solution satisfying $u \mathbf{D}_u - \mu \mathbf{D}_u \mathbf{D}_u = f_{\mu}$ at a reduced set of collocation points $\mathbf{C}_R$.

3. Numerical results

In this section, we demonstrate the accuracy and efficiency of the proposed methods on a 2D diffusion-type problem with zero Dirichlet boundary condition [3]: $(1 + \mu_1 x)u_{xx} + (1 + \mu_2 y)u_{yy} = e^{4xy}$ on $\Omega = [-1, 1] \times [-1, 1]$. Our truth approx-

5 In more complex situations, where more points are needed, one may propose a greedy method to capture the best positions of points $G_k$ so that $P_{G_k} = (L_{\mathcal{N}}(\mu^G_k))^{-1}$ will be computed. Note however that, as is often the case, the greedy method will start to pick the corner in the first iterations.
imotions are generated by a spectral Chebyshev collocation method [9,4]. For \( C^N \), we use the Chebyshev grid based on \( N_x \) points in each direction with \( N_x^2 = N \). We consider the parameter domain \( D \) for \( (\mu_1, \mu_2) \) to be \([-0.99, 0.99]^2\). For \( \Sigma \), they are discretized uniformly by a 64 \( \times \) 64 Cartesian grid.

In Fig. 1 (left), we show that while the non-parametric preconditioning \( p^{hc} \) give non-uniform improvement, the parametric preconditioning \( p^I(\mu) \) improves effectivity indices by one order of magnitude. Fig. 1 (right) shows that the \( p^{hc} \) preconditioning operator improves the \( L_2 \) norm of the error, but worsens the \( H^1 \) norm. In comparison, \( p^I(\mu) \) improves the error in \( L^2 \) norm without significantly degrading (in some cases improving) the error in \( H^1 \) norm. Finally, we plot the stability constant of these preconditioned operators as a function of the parameter in Fig. 2. We clearly see that \( p^I(\mu) \) is most efficient in terms of enforcing the parametric stability number uniformly close to 1. We also tested diagonal preconditioning \( p^I_D(\mu) \) (not reported here) by using the same interpolating procedure as \( p^I(\mu) \) and replacing the inverses of the full operators by the inverses of the diagonals. Clearly \( p^I_D(\mu) \) is cheaper to compute than the other preconditioners, but its performance is significantly worse than \( p^I(\mu) \) and even worse than \( p^{hc} \).

For the preconditioned RCM, we can see from Fig. 3 that the error for the least squares approach is one order of magnitude better in the worst-case scenario. The empirical reduced collocation approach is related to interpolation. So
there is no reason to expect the error to decrease monotonically and, actually, it does not. However, the error is smaller and, more importantly, converges much more stably.

4. Concluding remarks

We propose and test two analytical preconditioning strategies in the context of the reduced collocation method. The parameter-dependent one is shown to be capable of offline-online decomposition, improving both the quality of error estimation uniformly on the parameter domain, and enabling the preconditioned reduced collocation method to converge much faster and more stably than the non-preconditioned version.
