Abstract
The paper presents the results of studies of the structure and properties of a wire with a diameter of 0.5 mm from an alloy of the Al-REM system with a rare-earth metal content of 7–9%. Wire obtained as a result of the implementation of the technology of its manufacture using the methods of casting into an electromagnetic mold (EMM), continuous extruding, and drawing. The rheological properties of the metal of continuously cast round billets from the experimental alloy obtained using an electromagnetic mold are determined. The modeling and analytical assessment of the possibility of carrying out the process of combined rolling-extruding (CRE) of such billets in a closed box-type roll groove of a continuous extruding unit are carried out. The features of metal shaping have been studied. The temperature-speed and technological parameters were found at which the CRE process can be carried out in a stable mode of operation. Data have been obtained for the forces acting on the die and rolls during rolling-extruding. The results of experimental studies of the process of obtaining longish deformed semi-finished products from an experimental alloy on the laboratory unit CRE-200 and the pilot plant unit CRE-400 are presented. The structure of the metal has been studied; data on the ultimate tensile strength, yield strength, relative elongation, and electrical resistance of hot-extruded rods and wires in cold-worked and annealed states have been obtained. It was found that the proposed processing modes make it possible to obtain by the method of combined rolling-extruding rods with a diameter of 9 mm in industrial conditions from longish billets with a diameter of 18 mm, cast by means of EMM. Wire in a cold-deformed and annealed state with a diameter of 0.5 obtained by drawing from the rods with a diameter of 9 mm from an experimental alloy of the Al-REM system containing 7–9% rare-earth metals with the required physical and mechanical properties.

1 Introduction
Deformed longish semi-finished products in the form of rods, wire rods, and wires made of aluminum alloys are widely used for the manufacture of electrical products [1–5]. High-performance properties in combination with low specific mass and high electrical conductivity make it possible to use cable products in power lines, aviation, and space technology. In the manufacture of electrical conductors for aircraft operating at elevated temperatures (up to 250 °C), high-alloyed aluminum alloys with rare earth metals (REM) are most used, which
have the necessary complex of mechanical, electrical properties, and thermal resistance. One of these alloys is an aluminum alloy of the Al-REM system with a rare-earth metal content of 7–9%, from which a wire with a diameter of 1.0–1.2 mm was produced using a multistage granular technology [6, 7]. That technology including 17 technological stages. Since these alloys have a limited resource of plastic properties, the use of traditional technologies for obtaining deformed semi-finished products from them (for example, discrete extrusion on horizontal hydraulic extruders) has not found wide application in industry. In addition, this led to a high cost of semi-finished products due to the high labor intensity and high energy consumption for their production.

Recently, a need has arisen for a wire of small diameters of 0.1–0.5 mm made of these alloys, which has the following complex of physical and mechanical properties: the ultimate tensile strength under tension should be within the range $R_{m} = 180–200$ MPa; ultimate tensile strength at a temperature of 250 °C in the range of $R_{m} = 100–120$ MPa; the elongation to failure is $\lambda = 8–14$%; electrical resistance $\rho = 0.03000–0.03200$ Ohm·m/mm² (according to TS 1-809-1038-2018 [8]). Since the resource of plastic and strength properties of alloys of the Al-REM system is limited, it is required to develop a technology for manufacturing such a wire, obtained on drawing machines for fine and finest drawing, having the required set of properties.

Despite the fact that the study of the structure, properties, and processing technologies of the alloys Al-REM system is devoted to the works of many domestic and foreign scientists [1, 9–50], the task of creating an energy-efficient technology for producing wires with a diameter of 0.1–0.5 mm from these alloys still not resolved. Work [1] covers laboratory and industrial efforts of applying cerium for a purpose of developing aluminum alloys with superior properties. The binary Al-Ce, ternary Al-Ce-X, and higher-order phase systems are reviewed with a focus on the aluminum-rich sections. In work [9], technologically important eutectic transformation in Al–Ce binary alloys, containing from 5 to 20 wt.% Ce and ranging from hypo- to hypereutectic compositions, was examined along with the microstructure and properties of its solidified product. The advantages of REM in aluminum alloys are described in detail in works [1, 9, 10, 15–19].

The influence of REM in aluminum alloys on mechanical properties is considered in the works [20, 26–32, 34, 37–40, 43–45, 47, 48]. The influence of REM in aluminum alloys on electrical conductivity is considered in the works [20, 25, 31, 33, 34, 40, 42–45, 48]. The Ce content from 0.05 to 0.16 wt.% in the aluminum alloy is beneficial for increasing the electrical conductivity and tensile strength, since Ce reduces the solubility of solid impurity elements (Fe, Si) in the aluminum matrix.

The use of high-alloyed alloys of the Al-REM system also provides significant advantages if it is required to increase the strength properties of the alloy, although this leads to a decrease in electrical conductivity [43–48].

At the same time, recently, in order to obtain longish semi-finished products from aluminum alloys, technologies have been developed for continuous casting of ingots of small cross-section into an electromagnetic mold (EMM) and their subsequent deformation on installations for continuous extrusion Conform [61, 62] or combined rolling-extruding (CRE) [60, 63–65] and drawing [4, 22–24, 50–65]. The use of such technologies can lead to the solution of these issues and the production of small-diameter wire with the required set of operational properties. Therefore, an urgent scientific and technical problem is the development of new technologies of combined processing for obtaining longish semi-finished products from high-alloyed alloys of the Al-REM system.

Therefore, the purpose of the research was the development of technical and technological solutions for the production of wire with a diameter of 0.1–0.5 mm from an experimental aluminum alloy with an REM content of 7–9% with the required level of physical, mechanical, and operational properties using continuous casting methods in electromagnetic mold, extruding, and drawing.

To achieve this goal, the following tasks were set and solved:

- Determination of rheological properties for cast billets from a test alloy and computer simulation of the process of CRE of a rod using a round billet from this alloy;
- Development of a methodology for determining the feasibility and power parameters of the CRE process in a box gauge of a billet with a circular cross-section from an experimental alloy obtained in EMM;
- Carrying out experimental studies of deformation force parameters for continuous extruding of rods from an experimental alloy on CRE units;
- Development of wire drawing routes and annealing modes when using rods manufactured on CRE units;
- Carrying out studies of the structure and properties of rods and wires from the experimental alloy obtained using the methods of continuous casting into EMM, continuous extruding and drawing, founding the patterns of their change from the parameters of deformation processing.
- Development of new technologies for combined processing and devices for its implementation in order to obtain wire from an experimental alloy with a given level of physical and mechanical properties and approbation of research results in industrial conditions.

2 Materials and method of carrying out research

For the production of high-quality cast billets with a small cross-section, the continuous casting method using EMM
has been increasingly used. At the same time, due to high cooling rates and the absence of metal contact with the walls of the mold, it is possible to obtain billets of small diameters (5–18 mm) with a fine-grained structure and increased plastic properties [6, 11–14, 51–55]. The ingot obtained in the EMM has a dendritic parameter 100 times less than when casting into a slip mold and is comparable to the structure of granules (Table 1). In addition, dendritic segregation and non-metallic inclusions are practically absent in these ingots, which is not achieved even with the use of granular technology. This makes it possible to use continuously cast billets of small cross-section for a high-performance continuous process of CRE and to obtain longish extruded products from low-plasticity aluminum alloys for subsequent wire drawing.

To determine the rheological properties of such continuously cast billets with a diameter of 12 mm from a test 01417 alloy (Table 2), the method of hot twisting of samples was used [66, 67] in a wide range of temperature, rate, and degree of deformation (Fig. 1).

To determine the rheological properties according to the method developed at the Department of Metal Forming of School of Non-ferrous Metals and Materials Science of the Siberian Federal University (SibFU), torsion was carried out on the existing unit in different modes in a wide range of temperature, rate, and degree of deformation (Fig. 1). The analysis of the obtained dependences showed that the shape of the hardening curves for the 01417 alloy has a typical character, as for most other aluminum alloys. With an increase in the test temperature, the hardening rate increases. The obtained data on the rheological properties were used for computer modeling of the CRE process in a box gauge of a round billet. The diagram of the process is shown in Fig. 2, using the laboratory CRE-200 unit (Table 3).

When modeling using the DEFORM-3D complex, the following conditions were accepted: the material of the rolls and dies is absolutely rigid; the diameter of the billet is 12 mm, and the diameter of the extruded product is 5 mm; the process takes place at a constant ambient temperature of 20 °C; the temperature of the billet is taken equal to 550 °C, and the temperature of the tool is 200 °C; for calculations, the billet was divided into 10,000 finite elements; the frequency of rotation of the rolls \( \omega \) varied at two levels (4 and 8 rpm); Siebel friction coefficient was, on the contact surface of the roll—a billet equal 0.8, and at the border of the roll—a die equal 0.5 [21].

The microstructure of the metal was investigated using an Olympus GX51 optical microscope, an Axio Observer.A1m light microscope and an EVO 50 scanning electron microscope with an Inca Energy 350 energy dispersive spectrometer. Mechanical properties were determined using Walter + Bai AG LFM 400 kN universal testing machines (for cast billets and extruded bars), LFM 20 kN, and WDW-20 with a

force of 20 kN (for wire). Electrical resistance $\rho$ was measured on samples 1 m long using a “Vitok” ohmmeter.

To measure force indicators during experimental studies on the CRE-200 unit, strain gauge equipment was used. It includes CWW-50 and CWW-100 force sensors with a maximum allowable compression force of 500 kN and 1 MN and a ZetLab ZET 017-T8 strain gauge station.

3 Results and discussion

Simulation results obtained using the DEFORM-3D software package is shown in Fig. 3.

One of the design features of the tooling of the CRE-200 unit is that the diameter of the roll with the protrusion along the bottom is 162.7 mm, and the diameter of the ridge roll is 214 mm. The consequence is the realization of different linear velocities of movement of the surfaces of the tool at the contact billet—the bottom of the groove (position 1, Fig. 3a, e) and billet—protrusion of the roll (position 2, Fig. 3a, e). At an angular speed of rotation of the rolls $\omega = 4$ rpm, the values of linear velocities on these surfaces will be 34 mm/s and 44.8 mm/s respectively. This leads to the bending of the metal in the direction of the roll of a smaller diameter (roll with the groove) and the absence of contact of the billet with the ridge of the roll with a protrusion at the initial stage of the process (position 3, Fig. 3a). Furthermore, the billet rests against the die from the side of the roll with the groove, bends, and fills the extrusion zone (Fig. 3f). At the same time, an increase in the force acting on the rolls and the die is observed.

Analysis of the simulation results showed that the shape change of metal during the processing of billet with a circular cross-section with a diameter of 12 mm in a closed box gauge on the CRE-200 unit differs significantly from the shape

Fig. 3  Shaping of metal and temperature distribution along deformation zone in the simulation of the CRE process of a billet with a circular cross-section: a the initial stage of deformation at $\omega = 4$ rpm; b rolling stage at $\omega = 4$ rpm; c extruding stage at $\omega = 4$ rpm; d extruding stage $\omega = 8$ rpm; e metal forming at the end of the rolling stage at $\omega = 8$ rpm; f metal forming at the stage of extruding at $\omega = 8$ rpm
change of a square billet. At the initial stage of the process at \( \omega = 4 \) rpm (Fig. 3a), the billet with incomplete contact is captured by the rolls and compressed by the bottom surface of the roll with a groove and the ridge of the roll with a protrusion. It was found that at a given rotation frequency of 4 rpm, the rolls slip, and a gradual decrease in the temperature of the billet in the extruding zone is observed (Fig. 3b) which can lead to a halt in the process. In this case, the degree of metal reduction in height during rolling is 44%, which is lower than the value of 50% recommended in earlier studies [21]. This is due to the fact that in the rolling zone, there is a decrease in the contact area of the billet with the rolls along the corner elements of the groove and the value of the force supplied by the rolls decreases. At the same time, the degree of metal reduction in height during rolling (44%) does not exceed 50%. Furthermore, the billet metal reaches the die and extruded out, filling the caliber. When the pressure in the extruding zone is sufficient for extrusion, the metal is squeezed out in the form of a rod through a calibrating hole in the die (Fig. 3c, d).

Analysis of the energy-power parameters of the process obtained during the simulation at \( \omega = 4 \) rpm shows that a number of characteristic stages of the CRE process can be distinguished (Fig. 3a, c): the stage of rolling (steps 1–350), the initial stage of extrusion (steps 350–500), and extruding rod stage (steps 500–900). At the same time, at step 592 of the simulation, there is a significant decrease in the force on the rolls. The temperature of the billet in front of the die is 240–280 °C which indicates the slip of the billet relative to the rolls and a decrease in the stability of the process. Simulation of the process at \( \omega = 8 \) rpm (Fig. 3d) shows that the forces acting on the rolls and the die in the direction of the Y-axis have lower values at high values of the billet temperature in the zone of the smallest section of the caliber and extruding.

It should be noted that for the cases of the process at a circumferential speed of rotation of the rolls \( \omega = 4 \) rpm (Fig. 3c) and \( \omega = 8 \) rpm (Fig. 3d) the greatest force in the direction of the Y-axis on a roll with a groove—\( vr \), roll with protrusion—\( vv \), and die—\( m \) reached at the moment of extrusion of the press-product.

To analyze the deformation of the metal in the central part of the billet during the simulation, the method of coordinate grids with a cell size of 2.7×2.7 mm was used. Pictures of metal shaping at the end of the rolling stage and at the extrusion stage are shown in Fig. 3e, f.

Analysis of the metal temperature distribution showed that at the initial stage of the process, the billet is cooled from 550 to 450 °C. Its temperature in the extruding zone at the start of the extrusion of the rod is 330–340 °C. Further deformation leads to a decrease in the temperature in the extruding zone to 240–280 °C. Therefore, for the case of the implementation of rolling-extruding at a roll rotation frequency of 4 rpm with a rolling reduction ratio of less than 50%, it is possible to stop the metal deformation process.

An increase in the rotation speed of the rolls to 8 rpm significantly reduces the heat loss of the billet due to the shorter time of its contact with the rolls and the die having a temperature of 200 °C. So in the plane of the smallest cross-section of the caliber, the average temperature of the billet is 500 °C, and at the stage of pressing and the beginning of extrusion of the rod, it varies in the range of 410–445 °C. Further extrusion (Fig. 3d) leads to a decrease in the temperature of the metal in the extruding zone to 320 °C and an increase in the temperature of the metal to 375 °C which is typical for the steady-state of CRE process.

Thus, for a stable course of the combined rolling-extruding process on the CRE-200 unit of a billet with a diameter of 12 mm, the following technological parameters of processing modes can be recommended based on the simulation results: billet temperature 550 °C, temperature of rolls and die 200 °C, roll rotation frequency 4–8 rpm; reduction in height when rolling is not less than 50%.

As it was revealed during the simulation the possibility of carrying out the process CRE when using a round billet differs significantly from the deformation of a square or rectangular billet in a closed box caliber. Rolling such billets in a rectangular box gauge is possible only if certain conditions are met. It was found that for the guaranteed implementation of the process, it is necessary that the groove width of the box gauge is 5–15% greater than the diameter of the round billet which allows, on the one hand, providing an unhindered supply of the heated billet in the gauge. And on the other hand, it allows controlling the guaranteed filling of the gauge with metal in width. When the width of the groove in comparison with the diameter of the billet is less than 5%, due to the widening of the metal when it is heated, the supply of the billet in the rolls and its capture by the rolls becomes difficult. To fill the caliber when the difference between the width of the groove of the roll and the diameter of the billet is more than 15%, large height reductions are required during rolling. This significantly increases the energy and power costs during metal deformation. In addition, for the implementation of the CRE process, it is necessary to have a given height on a roll with a ridge protrusion which should be determined. When rolling-extruding a billet with a circular cross-section, the redistribution of metal in the caliber occurs unevenly. And during rolling, the caliber may not be completely filled. This can lead to a decrease in the contact forces of friction and, as a consequence, to slip of the rolls relative to the billet. As a result, the CRE process becomes unstable and the metal is not squeezed out through the die. In order to eliminate this drawback and ensure a stable process of metal extrusion due to the guaranteed filling of the caliber with metal during rolling, it is proposed to determine the height of the roll ridge with a protrusion based on the condition of equality of the areas of the initial round billet with a diameter \( d_0 \) and the area of the upset rectangular billet after rolling in the minimum section of the caliber (Fig. 2). Then, taking into account the specified distance
between the roll barrels $\delta$, the height of the roll ridge with the protrusion $h_p$ can be found by the following formula [63]:

$$
    h_p = \delta + d_0 - \frac{0.25\pi d_0^2}{b}
$$  \hspace{1cm} (1)

And the condition for the feasibility of the CRE process for the case of deformation of a billet with a circular cross-section will be written in the form:

$$
    h_{pe} \geq h_p,
$$  \hspace{1cm} (2)

where $h_{pe}$ is the experimental value of the roll protrusion height incorporated in the design of the combined processing unit (Table 3).

To calculate the force parameters, the data on the rheological properties of the experimental alloy was used (Fig. 1) and took into account the increase in energy consumption due to the cooling down of the billet during its supply in the rolls and the formation of a barb when the metal penetrates between the die and the rolls.

The force supplied by the rolls was determined by the formula [63]:

$$
    P_r = 0.017k_b\sigma_{Sav}D\left(\sqrt{\frac{\Delta h}{0.5D}} + \beta\right)(b + h)
$$  \hspace{1cm} (3)

where $\sigma_{Sav}$ is the average resistance of the metal to deformation, taking into account the cooling of the metal in the rolls; $k_b$ the coefficient taking into account the thickness and temperature of the barb; $D$ the average roll diameter; $\Delta h$ the absolute rolling reduction; and $\beta$ the distance angle of the die surface from the common axis of the rolls (Fig. 2).

The force acting on the die was found by the formula:

$$
    P_d = 1.57k_b\sigma_{Sav}(1.642F_d\ln\mu + 0.5\mu d_d h_b)
$$  \hspace{1cm} (4)

where $\mu$ is the extrusion ratio during extruding; $l/b$, the size of the working belt of the die; and $F_d$ the area of the pressed billet in front of the die surface.

As a result of calculations using the obtained formulas for the same caliber and dimensions during extruding (Table 4), it was found that the force acting on the rolls during processing on the industrial CRE-400 unit is higher than on the CRE-200 unit. This is due to the fact that the rolling diameters of the rolls in this case are larger, and accordingly, the length of contact of the rolls with the metal is also larger. It has also been found that for the conditions of processing a round billet on CRE units, the clamping force (Table 3) is not enough to press the die and the process will be unfeasible. Therefore, the temperature $T_b = 550^\circ\text{C}$ should be chosen, then the maximum force required for extruding a rod with a diameter of 5 mm will not exceed 241 kN.

Figure 4 shows a comparison of the graphs of the calculated force parameters of the continuous extruding process for laboratory processing conditions on the CRE-200 unit (caliber 7×15 mm) and for industrial conditions on the CRE-400 unit (caliber 10×21 mm) at different billet temperatures (Table 4). It can be seen that for the CRE-400 unit, the recommended parameters for experimental studies ($T_b = 550^\circ\text{C}$, $\xi = 0.5\text{ s}^{-1}$) provide optimal power loading of the equipment over the entire range of values of the extruding ratio. On the basis of the calculations, technological recommendations were prepared for laboratory research on the CRE-200 unit and pilot-industrial research on the production of rods from alloy 01417 on the CRE-400 unit using continuously cast billets of various diameters obtained using an electromagnetic mold.

To carry out experimental studies, the design of a new unit for continuous casting, rolling, and extruding of metal was proposed. The unit includes a mixer furnace, an electromagnetic mold, and a deforming unit consisting of a roll with a protrusion and a roll with a groove forming a working caliber, at the exit from which a die with wedge-shaped cavities for cooling is installed, pressed against the rolls using a hydraulic cylinder. A cooling device, a universal rolling stand, and a device for product winding are installed in series behind the deforming unit [21–24, 49, 63, 64]. In order to use it for rolling a billet with a circular cross-section, it is proposed to improve the deforming unit of the installation by making a box gauge, in which the groove width of the roll with the groove is greater than the billet diameter by 5–15%. And the ridge of the roll with the protrusion to perform the given height taking into account the distance between the roll barrels. That distance is calculated by formula (1).

To study the influence of casting and annealing modes on the properties and structure of rods from the investigated alloy, obtained using EMM, at the LLC “Research and Production Center for Magnetic Hydrodynamics” (Krasnoyarsk), experimental billets were made at various casting temperatures of 670, 740, and 780 °C and casting speeds of 4.4, 10.8, and 14.5 mm/s. The billets were heat-treated at temperatures of 400, 450, 500, and 550 °C for 2, 4, and 8 h. The analysis of the microstructure of the billets (Fig. 5) showed that with a decrease in the casting temperature the internal structure of the grain becomes coarser. The branches of dendrites become thicker and the parameter of the dendritic cell slightly increases. Annealing at a temperature of 550 °C causes degeneration of the eutectic and a uniform distribution of rare-earth aluminides is observed in the microstructure.

The results of determining the grain size in the cast billets of the experimental alloy showed that it is not the same over the section. In some areas of the peripheral zone, a fine-grained structure with a grain size of 31–64 μm is observed and a coarse-grained structure with a grain size from 337 to

---

**Fig. 4** Graphs of changes in the power parameters of the CRE process for the CRE-200 and CRE-400 units with different caliber sizes: a, b $T_b = 480$ °C; c, d $T_b = 550$ °C; solid lines, $\xi = 0.5$ s$^{-1}$; broken lines, $\xi = 1.5$ s$^{-1}$

**Fig. 5** Microstructure of annealed billets at temperature $T_a = 550$ °C with a diameter of 12 mm from a test alloy 01417 with casting speed of 10.8 mm/s and different temperatures $T_c$: a $T_c = 670$ °C; b $T_c = 740$ °C; c $T_c = 780$ °C; ×1000
1410 μm is observed across the section. Therefore, hot deformation is required to work out the structure.

The properties of the obtained cast rods are given in Table 5.

The analysis of these data showed that the strength properties of cast billets increase with an increase in the casting speed, while the plasticity of the billets decreases, but remains at a fairly high level (12.4–15.5%). With an increase in the annealing temperature to 550 °C and a duration of 8 h, the elongation to failure increases to 38%, the ultimate tensile strength decreases to 126 MPa as compared to the cast state. However, the surface of the billets turns from shiny to matte gray.

In order to obtain billets for wire drawing the method of combined rolling-extruding was used [21–24, 49, 63, 64]. Experimental studies were carried out on a laboratory unit CRE-200 and an experimental-industrial unit CRE-400 (Table 6). During the experimental rolling-extruding on the CRE-200 unit, the following technique was used. Several continuously cast billets 12 mm in diameter were simultaneously heated in an electric chamber furnace to a temperature of 550 °C and held for 10–15 min. The rolls and the die were heated to a temperature of 200 °C, at which the rolls of the CRE-200 unit were brought into rotation at a speed of 4 rpm. The billets were sequentially set in the roll caliber, while the metal was pressed in height during rolling, pressed out in front of the matrix, and squeezed out through it in the form of a rod. Then the rotational speed was increased to 8 rpm and the experiments were repeated.

The results of experimental studies of force parameters for obtaining rods with a diameter of 5 mm from a billet with a diameter of 12 mm from an experimental alloy in comparison with the calculated data are presented in Table 7.

Furthermore, from extruded rods with a diameter of 5 mm on a chain drawing mill (Table 8) a wire with a diameter of 0.5 mm was obtained according to the developed route, subjecting intermediate annealing to a semi-finished product with a diameter of 2.5 mm.

The results of testing the mechanical properties of the obtained cast and deformed semi-finished products from the experimental alloy are presented in Table 9.

The patterns of their change with an increase in the degree of deformation correspond to the traditional concepts of the theory of metal forming, while the ultimate tensile strength increases and elongation to failure decreases (Fig. 6) [22].

It was found that annealing the wire at a temperature of 500 °C and a holding time of 1 h leads to a decrease in the ultimate tensile strength to a value of 137 MPa and an increase in the relative elongation to 19.1%. Even higher ductility (elongation to failure 23.6–28.8%) is possessed by a wire made from a billet obtained on an CRE unit with a roll rotation frequency

### Table 5

| Force, kN | $\xi$, s$^{-1}$ | Calculated data | Experimental data | Deviation, % |
|-----------|-----------------|-----------------|-------------------|--------------|
| $P_r$     | 0.5             | 314             | 348               | 9.8          |
|           | 1.5             | 382             | 387               | 1.3          |
| $P_d$     | 0.5             | 199             | 181               | 9.0          |
|           | 1.5             | 241             | 218               | 9.5          |
of 8 rpm, which allows further cold deformation of the metal to obtain a wire with a diameter of about 0.1–0.2 mm. Measurements of the electrical resistance showed that their values for all modes of processing wire from an experimental alloy with a diameter of 0.5 mm in the annealed state are within the required limits 0.02919–0.03054 Ohm·mm²/m.

Metallographic studies of extruded rods (Fig. 7) showed that they have a uniform fine-grained structure (Fig. 7a). The size of inclusions is insignificant and does not exceed 7 μm. After hot deformation, the consequences of dendritic segregation were eliminated, and instead of dendritic cells, there was a uniform and dispersed distribution of REM aluminides over the cross-section of the rods. The structure of a wire with a diameter of 0.5 mm in various states is shown in Fig. 7b, c. The analysis of the research results allowed concluding that the wire made from a rod obtained on CRE unit with a roll rotation frequency of 4 rpm has the required set of mechanical and electrical properties after annealing at a temperature of 500 °C and holding time of 1 h.

In order to obtain pilot batches of wire from alloy 01417 with a diameter of 0.5 mm with the required complex of physical and mechanical properties at the enterprises of LLC “Plant of Modern Materials” and LLC “Alliance 2008” (Krasnoyarsk) on the CRE-400 unit, hot-extruded rods were obtained for drawing with a diameter of 9 mm. At the same time, based on the calculation of power costs and the feasibility of the process, as well as recommendations for the processing and annealing modes, the diameter of the continuously cast billet obtained in the EMM, the temperature and technological parameters of continuous extruding and subsequent drawing were selected.

On the CRE-400 unit, a coil of continuously cast billet with a diameter of 18 mm from an experimental alloy weighing 100 kg obtained in the EMM was processed. In accordance with the developed technique, continuously cast billets were heated to a temperature of 550 °C in an electric furnace and sent to rolls heated to a temperature of 200 °C. The die, also heated to 200 °C, was pressed against the rolls using a hydraulic cylinder and rolled-extruding was carried out. The resulting rod with a diameter of 9 mm was subjected to drawing to a diameter of 0.5 mm with intermediate annealing on a commercial drum-type drawing mill. It was found that extruding a billet heated to 550 °C at a roll and die temperature of 200 °C and a roll rotation speed of 8 rpm can lead to the formation of temperature cracks along the length of the extruded rod. Subsequent experiments made it possible to recommend a roll rotation frequency of 2–4 rpm for the CRE-400 unit. The recommended technological parameters of the CRE process,

Fig. 6 Mechanical properties of deformed semi-finished products from a test alloy 01417 before (a, b, e, f) and after (c, d, g, h) annealing at different roll speeds: a, c, e, g 4 rpm; b, d, f, h 8 rpm

Fig. 7 Microstructure of a rod with a diameter of 5 mm (a) and a wire made of alloy 01417 with a diameter of 0.5 mm in deformed (b) and annealed (c) states, ×1000
thus, ensured the ability of the extruded rods to draw, which proceeded stably and without breaks while the wire had a shiny high-quality surface.

Electron microscopic studies of the microstructure of cold-deformed wire with a diameter of 0.5 mm (Fig. 8) were carried out in order to determine the particle size of REM aluminides and their distribution over the cross-section of the wire obtained under industrial conditions.

These data were necessary to determine their effect on the physical and mechanical properties of the wire and to justify the choice of the mode of its final annealing. The microstructure of the wire at enlargement of 20,000 times (Fig. 8a) is characterized by the presence of dispersed and fairly uniformly distributed REM aluminides against the background of an aluminum solid solution. The determination of the size of aluminide particles with enlargement of 50,000 (Fig. 8b) showed that they are 96–214 μm. Figure 9 shows the results of determining the elemental composition of the wire and the microstructure using the COMPO and SEI contrast, which shows an aluminum matrix and light particles of lanthanum and cerium aluminides.

The results of testing the mechanical properties of the wire from the experimental alloy before and after the final annealing in different modes are presented in Table 10.

The developed modes of casting, continuous extruding, drawing, and annealing, thus, made it possible to obtain commercial batches of wire with a diameter of 0.5 mm (Fig. 10) with the required level of properties.

For independent tests of the properties, measurements of the ultimate tensile strength, elongation to failure, and electrical resistance at room temperature were carried out for 5 coils of the wire obtained at “Special Design Bureau of the Cable Industry” Ltd. (Moscow, Russian Federation). The test results confirmed the conclusion that the physical and mechanical properties of a wire with a diameter of 0.5 mm from an experimental alloy meet the requirements. According to test results, the ultimate tensile strength for a wire with a diameter of 0.5 mm in the annealed state should not be lower than 142.5 MPa, the elongation to failure not lower than 8%, and electrical resistance not higher than 0.03200 Ohm·mm²/m.

The study of the heat resistance of a wire with a diameter of 0.5 mm from an experimental alloy was carried out in the testing laboratory of mechanical and climatic tests of samples, materials, and components of “Research Complex of Technological Support Center” Ltd. (Novosibirsk, Russian Federation) at various temperatures of 180, 240, and 310 °C and holding times of 1 and 400 h. As a result of the tests, it was found that the wire from the experimental alloy submitted for examination, produced according to the developed technology, meets the requirements.

4 Conclusions

Thus, as a result of the research, the following main results were obtained:

1. Studied the rheological properties of continuously cast billets with a diameter of 12 mm from an experimental alloy of the Al-REM system with a rare-earth metal content of 7–9%, made according to various casting modes in an electromagnetic mold. Obtained graphical dependences of the resistance of metal deformation on temperature, rate, and degree of deformation in a given experimental condition the range of their variation. For the investigated alloy at a temperature of 320 °C and a rate of 0.5 s⁻¹, an increase in the deformation rate from 0.5 to 10 s⁻¹ leads to an increase in the resistance to deformation 1.3
times, and at a temperature of 550 °C, 2.3 times. The intensity of softening of the investigated alloys increases with an increase in the deformation rate and decreases with an increase in the temperature of experiment.

2. A computer 3D model of the combined rolling-extruding process was created for deformation of a billet with a circular cross-section, and with its help, the features of the shape change and temperature distribution in the deformation zone at different roll rotation frequency were studied using data on the rheological characteristics of the experimental alloy. Thus, for the stable course of the combined rolling-extruding process at the CRE-200 unit of continuously cast billets with a diameter of 12 mm from alloy 01417 obtained using EMM, the following technological parameters of the processing modes can be recommended: billet temperature 550 °C, rolls and extruding die temperature 200 °C, roll rotation frequency 8 rpm. For drawing ratio during extrusion 15.3, the height reduction during rolling is recommended to be increased to 50%.

3. A method is proposed for the experimental and analytical assessment of the feasibility of the CRE process and for calculating the force characteristics during deformation of a billet with a circular cross-section, with the use of which the design parameters of the roll and extruding tool are determined, as well as the technological modes of continuous extruding for experimental research. For the CRE-400 unit, the recommended parameters for experimental studies \((T_b = 550 °C, \xi = 0.5 \text{ s}^{-1})\) provide optimal power loading of the equipment over the entire range of values of the extruding ratio. In order to use it for rolling a billet with a circular cross-section, it is proposed to improve the deforming unit of the installation by making a box gauge.

### Table 10

Physical and mechanical properties of a wire with a diameter of 0.5 mm from a test alloy 01417 obtained using the CRE-400 unit

| Annealed, \(T = 450 °C, \tau = 4 \text{ h}\) | 160                   | 15.6                            | 0.03138 |
|                                 | 157                   | 15.2                            | 0.03143 |
|                                 | 161                   | 14.5                            | 0.03133 |
| Annealed, \(T = 500 °C, \tau = 4 \text{ h}\) | 162                   | 16.5                            | 0.03139 |
|                                 | 157                   | 16.8                            | 0.03132 |
|                                 | 158                   | 16.4                            | 0.03133 |
in which the groove width of the roll with the groove is greater than the billet diameter by 5–15%.

4. With the use of the developed technological modes of continuous casting in EMM, continuous extruding by the CRE method, bar rolling, drawing, and intermediate and final annealing, experimental studies were carried out to obtain a wire with a diameter of 0.5 mm from an experimental alloy in the laboratory conditions. Ultimate tensile strength $R_m = 120–155$ MPa, elongation to failure $A = 12.7–28.8\%$, electrical resistance $\rho = 0.02911–0.03054$ Ohm·mm$^2$/m.

5. At all stages of these experimental studies, the structure of the metal was investigated and the regularities of changes in the ultimate tensile strength, yield strength, elongation to failure, and electrical resistance of longish deformed semi-finished products in the form of hot-extruded rods and wires in cold-deformed and annealed states were found depending on the processing modes. Determination of the size of REM aluminide particles showed that they are 96–214 μm. The maximum plasticity ($A = 28.8\%$) required for the further production of wire with a diameter of up to 0.1 mm, and the minimum value of the electrical resistance ($\rho = 0.02911$ Ohm·mm$^2$/m) is characterized by a wire with a diameter of 0.5 mm obtained by the EMM+CRE (at 550 °C and $\omega = 4$ rpm) method with subsequent drawing, annealed at a temperature of 500 °C and holding time 1 h.

6. Using the CRE-400 unit in industrial conditions, rods with a diameter of 9 mm were extruded from a continuously cast billet with a diameter of 18 mm, obtained using EMM, from which pilot batches of wire with a diameter of 0.5 mm were made from an experimental alloy of the Al-REM system containing rare-earth metals of 7–9% with the given physical and mechanical properties, while new deformation modes of continuous extruding and drawing routes, as well as modes of intermediate and final annealing have been developed. The recommended annealing temperature for the wire with a diameter of 0.5 mm obtained using CRE-400 unit is 400–500 °C with a holding time of 4 h. The properties of the wire correspond to TS 1-809-1038-2018.
