ABSTRACT
We present a theoretical investigation of multifilter (U, B, V, I and K) light and radial velocity curves of five classical Cepheids in NGC 1866, a young massive cluster of the Large Magellanic Cloud. The best-fitting models accounting for the luminosity and radial velocity variations of the five selected variables, four pulsating in the fundamental mode and one in the first overtone, provide direct estimates of their intrinsic stellar parameters and individual distances. The resulting stellar properties indicate a slightly brighter mass–luminosity relation than the canonical one, possibly due to mild overshooting and/or mass loss. As for the inferred distances, the individual values are consistent within the uncertainties. Moreover, their weighted mean value corresponds to a distance modulus of $18.56 \pm 0.03$ (stat) $\pm 0.1$ (syst) mag, in agreement with several independent results in the literature.

Key words: stars: distances – stars: variables: Cepheids – galaxies: star clusters: individual: NGC1866.

1 INTRODUCTION
Classical Cepheids are considered the most important primary distance indicators within the Local Group. Their period–luminosity relation, discovered by Leavitt in 1912 (Leavitt & Pickering 1912) for Cepheids in the Small Magellanic Cloud and usually calibrated in the Large Magellanic Cloud (LMC; see e.g. Madore & Freedman 1991; Udalski et al. 1999), is now at the basis of an extragalactic distance scale (see e.g. Freedman et al. 2001; Saha et al. 2001, and references therein). Indeed, with the capabilities of the Hubble Space Telescope (HST), Cepheids have been observed at distances (up to $\sim 30$ Mpc), enabling the calibration of several secondary distance indicators capable to reach cosmological distances and to provide an estimate of the Hubble constant $H_0$ (see e.g. Freedman et al. 2001, for detailed discussion). In spite of the most recent relevant efforts in the direction of reducing the uncertainty on the Cepheid-based extragalactic distance scale (see e.g. Riess et al. 2011, 2012, and references therein), some systematic effects, including the effect of the host galaxy metal content, remain unsolved, and different authors keep to provide significantly different estimates of the Hubble constant (see e.g. Riess et al. 2012; Tammann & Reindl 2012, and references therein). The first crucial step for the calibration of the extragalactic distance scale is the distance to the LMC. Several methods have been adopted in the literature (see e.g. Molinaro et al. 2012; Walker 2012, and references therein) providing values that range from $\sim 18.1$ to $\sim 18.9$ mag. Systematic effects such as a non-negligible metallicity dispersion, differential reddening and a significant depth of the cloud are known to be at work.

In this context, classical Cepheids belonging to young stellar clusters in the LMC play an important role, being at the same distance and sharing the same age and chemical composition. Thanks to these advantages they offer a unique opportunity to investigate the uncertainties affecting both empirical approaches and theoretical scenarios. NGC 1866 is one of the most massive young clusters in the age range 100–200 Myr, and it has been the subject of a very long list of papers, starting with the pioneering ones by Arp & Thackeray (1967) and Robertson (1974). Subsequent authors focused on studying the cluster either as a testbed of stellar evolution theory (e.g. Brocato et al. 1989, 2003, 2004; Chiosi et al. 1989; Brocato, Castellani & Piersimoni 1994; Testa et al. 1999; Walker et al. 2001; Barmina, Girardi & Chiosi 2002), as a Cepheid host (Welch et al. 1991; Welch & Stetson 1993; Gieren, Richtler & Hilker 1994; Walker 1995; Gieren et al. 2000; Storm et al. 2005; Testa et al. 2007; Molinaro et al. 2012) or as a dynamical laboratory (Fischer et al. 1992). It has also been the subject of a strong debate over the presence of convective overshooting in intermediate-age stellar models, and on the fraction of binaries in the main sequences. Moreover, this cluster lies in the outskirts of the LMC, so that field contamination is not severe. The investigation of Cepheid properties in this cluster can provide crucial information for our understanding of the physics and the evolution of intermediate-mass stars. In particular the comparison with the predictions of pulsation properties based on hydrodynamical models is an important tool to constrain the individual distances and the intrinsic stellar parameters, without relying on stellar evolution models, and in turn independently constraining their physical and numerical assumptions. In particular, the
possibility to obtain this information from the direct comparison between modelled and observed light curves has been first claimed by Wood, Arnold & Sebo (1997) for classical Cepheids and by Bono, Castellani & Marconi (2000a) for RR Lyrae. Subsequent applications both to field and cluster pulsating stars, sometimes including the additional match of radial velocity or radius curves, have provided self-consistent results, also in agreement with independent estimates in the literature (see Bono, Castellani & Marconi 2002; Di Fabrizio et al. 2002; Marconi & Clementini 2005; Marconi & Deegl’Innocenti 2007; Natale, Marconi & Bono 2008; Marconi et al. 2010).

In this paper we present an accurate comparison between observed multifilter light and radial velocity curves for a sample of Cepheids in NGC 1866 and the theoretical counterparts based on non-linear convective models. The photometric and radial velocity data are introduced in Section 2, while the fitting procedure is described in Section 3. The results of our analysis are contained in Section 4 and include the best-fitting structural parameters, the comparison with spectroscopic data, the implications for the distance, including a critical discussion of the associated uncertainty, and the mass–luminosity relations (MLRs). Finally, Section 5 contains the conclusions of the paper.

2 THE DATA

The adopted photometric data include observations in the U, B, V, I, K light curves and radial velocity curves of all selected Cepheids.

Table 1. The period $P$, the apparent $V$ magnitude and the number of measurements for the $U$, $B$, $V$, $I$, $K$ light curves and radial velocity curves of all selected Cepheids.

| Name     | Period  | $V$ (mag) | $U$ | $B$ | $V$ | $I$ | $K$ | Rad. vel. |
|----------|---------|-----------|-----|-----|-----|-----|-----|-----------|
| HV 12197 | 3.143 742 | 15.91 | 3   | 69  | 87  | 38  | 35  | 38        |
| HV 12198 | 3.522 805 | 15.77 | 30  | 69  | 90  | 62  | 77  | 38        |
| HV 12199 | 2.639 181 | 16.09 | 34  | 157 | 199 | 172 | 54  | 39        |
| We 2     | 3.054 847 | 15.86 | 15  | 69  | 90  | 62  | 5   | 12        |
| V6       | 1.944 252 | 15.97 | 21  | 69  | 90  | 62  | 10  | 10        |

As for the radial velocities, we used data from Storm et al. (2004, 2005), Welch et al. (1991) and Molinaro et al. (2012).

Table 1 summarizes the adopted number of photometric and radial velocity measurements for the selected Cepheids.

We phased the light curves by requiring that the $B$-band maximum of light occurred at phase zero, while the maximum in the other bands were shifted in phase as expected (see e.g. Freedman 1988; Labhardt, Sandage & Tammann 1997). Similarly, the radial velocity curves were phased by requiring that their minimum occurred at phase zero.

3 MODEL FITTING

New non-linear convective pulsation models have been computed to reproduce the observed luminosity and radial velocity variations. The adopted theoretical framework is based on a non-linear radial pulsation code, including the non-local and time-dependent treatment of turbulent convection (Stellingwerf 1982; Bono & Stellingwerf 1994; Bono, Marconi & Stellingwerf 1999). The system of non-linear equations is closed using a free parameter, $\alpha_{\text{ml}}$, that is proportional to the mixing length parameter. Changes in the mixing length parameter affect, as expected, both the limit cycle stability (pulsation amplitudes) and the topology of the instability strip (Di Criscienzo, Marconi & Caputo 2004; Fiorentino et al. 2007). Similar approaches for the treatment of convective transport have been developed by Feuchtinger (1999), Buchler & Szabó (2007) and Olivier & Wood (2005). We remind here that the non-linearity and the inclusion of a non-local, time-dependent treatment of convection and of its coupling with pulsation allows us to accurately predict all the relevant observables of stellar pulsation, namely the complete topology of the instability strip for each selected pulsation mode, the accurate morphology of light, radial velocity and radius variations and the associated pulsation amplitudes.

The modelling of the observed light and radial velocity curves has been organized in three main steps.

(i) First, we constructed a set of models with fixed chemical composition ($Z = 0.008$, $Y = 0.25$, consistent with the abundances measured for Cepheids in NGC 1866; Mucciarelli et al. 2011), mass and period (equal to the observed one), varying the effective temperature and luminosity in order to reproduce the observed variations.

(ii) Once identified the best effective temperature from the previous step, we built a sequence of models at fixed chemical composition, period and effective temperature, by varying the mass and the luminosity in order to obtain the best-fitting model, reproducing simultaneously the multifilter light curves and the radial velocity one.

(iii) In some cases we also changed slightly the metal and helium abundance within current uncertainties on the LMC chemical composition.

Each model curve was phased in order to find the maximum of light in the $B$ band at phase zero. Afterward, for each model we calculated the shifts in magnitude and phase, which gave the best match between the theoretical light curves and the observational data. Specifically, for each model, we calculated the phase shift, $\delta \phi$, and the magnitude shift, $\delta M$, which minimized the following $\chi^2$ function:

$$\chi^2 = \sum_{i=0}^{N_{\text{band}}} \sum_{j=1}^{N_{\text{points}}} \left[ m_j^i - (M_j^\text{mod} (\phi_j^i + \delta \phi^i) + \delta M^i) \right]^2,$$

where the index $i$ runs over the number of photometric bands, $N_{\text{band}}$, and $j$ runs over the number of measurements, $N_{\text{points}}$. In the equation above we used a spline interpolation to evaluate the theoretical absolute magnitude $M_j^\text{mod}$ at the phase $\phi_j^i$, of the $i$th photometric measurement $m_j^i$, plus the shift $\delta \phi$. We note that the parameter $\delta M$ gives the distance modulus of the analysed Cepheid in the $i$th photometric band.

As for the radial velocity curves, we transformed the model pulsational velocity, $v^\text{puls}$, into radial velocity, $v^\text{rad}$, by using the projection
Two of these ‘secondary’ models have the same temperature of the best-fitting one and a varied value of the luminosity (and the mass) and vice versa, the other two models have a fixed value of the luminosity and a varied value of the temperature. These secondary models are used to define the errors on the parameters. In particular, we defined the ±1σ uncertainty interval as half of the difference between the parameters of the quoted ‘secondary’ models and the ones of the best-fitting model. Typically this corresponds to errors of ±12 K, ±0.1 M⊙ and ±0.01 dex in effective temperature, mass and luminosity, respectively.

To analyse the effect of the projection factor p on the fit of the radial velocity data, we also tried to vary it in the χ² function given by equation (3). The resulting best-fitting values of the p factor are listed in Table 2 together with all the other structural parameters derived from our analysis.

We also computed additional models varying the chemical composition but these tests did not improve the accuracy of the model fitting for none of the investigated Cepheids, suggesting the usually assumed Z = 0.008 for the metallicity of these stars. The results in Table 2 also show that the value of the assumed mixing length parameter (to close the non-linear system of dynamical and convective equations) that provides the best match is αml = 1.9–2.0 for fundamental variables and a slightly smaller value (αml = 1.8) for the first overtone one, in agreement with previous theoretical results based on the analysis of both Cepheid and RR Lyrae properties (see e.g. Bono et al. 2002; Di Criscienzo et al. 2004; Marconi & Clementini 2005; Fiorentino et al. 2007; Natale et al. 2008, and references therein).

Below, we describe the result of the fit of light and radial velocity curves for all the selected Cepheids.

4.1 We 2

The best-fitting model selection illustrated above is shown for the fundamental pulsator We 2 in Figs 1 and 2. The best-fitting model (central panels in the two figures) has a characteristic effective

factor p in the relation \( v_{\text{rad}} = -\frac{1}{p} v_{\text{puls}} \) and phased it in order to find its minimum value at phase zero. In the previous formula we fixed the projection factor to \( p = 1.27 \), obtained by using the mean period for the selected Cepheids (first overtone fundamentalized according to Feast & Catchpole 1997) in the equation \( p = 1.31 - 0.08 \log P \), by Nardetto et al. (2009).

Then, to match the model radial velocity variations with the data, we minimized the χ² function of an equation similar to equation (2), where the magnitude shift is replaced with the \( y \) barycentric velocity, namely

\[
\chi^2 = \sum_{j=1}^{N_{\text{points}}} \left[ v_{\text{rad},j} - \left( -\frac{1}{p} v_{\text{puls},j} (\phi_j + \delta \phi) + y \right) \right]^2. \tag{3}
\]

4 RESULTS

In the present section we discuss the results obtained from the fitting procedure. The match between the best-fitting models and the data is described for all the selected Cepheids. The derived structural parameters for all Cepheids are given and for some of them we performed a comparison with the results obtained from the spectroscopy. Finally, we will give the best-fitting distance moduli and reddening values and discuss the implications of the derived MLR.

4.1 Best-fitting models

For each Cepheid we identified a best-fitting model and other four models (hereafter ‘secondary’ models) which are the closest (in the sense of the value of the \( \chi^2 \) function) to the best-fitting one, according to a reasonable² selection of the model grid steps (typically 25 K in effective temperature and 0.02 dex in \( \log L/L_\odot \)).

² Smaller steps do not produce significant differences in the model properties and/or are within the numerical precision of the hydrodynamical code.
In each one of the three panels on the left, the $U$, $B$, $V$, $I$ and $K$ band observed light curves of the Cepheid We 2 are shown from bottom to top (empty squares). The data have been systematically shifted to be shown in the same plot. The radial velocity data of the same star are shown in the three panels on the right (empty squares). The solid lines represent the model matched to the data. The $U$-band model is plotted with dashed line because it will be excluded in our further analysis (see Section 4.3). The best fit (BF) is plotted in the central panels and the models corresponding to $T_{\text{BF}} - 2\delta T$ and $T_{\text{BF}} + 2\delta T$ are shown in the bottom and top panels, respectively. In the panels showing the radial velocity curves, the models with $p$ factor free to vary are also plotted (long dashed lines).

As evident in the top and bottom panels, a variation of 25 K in the temperature (at fixed luminosity) or 0.02 dex in the luminosity (at fixed temperature) worsen the match with the data. As mentioned above, we define the parameter uncertainty intervals as the half of the quoted variations. We also note that the chosen value of the projection factor $p = 1.27$ provides an excellent match of the model radial velocity with the plotted data, even if the best analytic match is obtained for $p = 1.23$.

4.1.2 V6

It is instructive to show the same plots than We 2 for the first overtone pulsator V6 (Figs 3 and 4). In this case we note that the best-fitting model is located very close to the first overtone blue edge, so that a shift of only 25 K towards higher effective temperatures (see the top panels of Fig. 3) almost quenches the pulsation. On the other hand when decreasing the effective temperature by 25 K (bottom panels of the same figure), the predicted amplitudes increase significantly.
Theoretical fit of Cepheids in NGC 1866

Figure 2. The same as Fig. 1 but with models corresponding to \( \log(\frac{L}{L_\odot})_{\text{REF}} - 2\delta(\log\frac{L}{L_\odot}) \) and \( \log(\frac{L}{L_\odot}) + 2\delta\log(\frac{L}{L_\odot}) \) for We 2.

beyond the observed ones. If we consider the effect of a variation in the stellar mass we note that the corresponding variation in the pulsation amplitudes is much smaller, even if non-negligible when computing the \( \chi^2 \) minimization.

The procedure of best fitting of the radial velocity curve, when considering the projection factor as a free parameter, provides the value \( p = 1.00 \), which is significantly different from 1.27 and smaller than other typical values adopted in the literature. A possible explanation might be a not sufficiently good quality of the data, but we note that similar results have been discussed by Natale et al. (2008) for \( \delta \) Cephei using a well-sampled radial velocity curve.

4.1.3 HV 12197

The two panels of Fig. 5 show the best-fitting result for Cepheid HV 12197. The \( U \) band is excluded from our analysis due to the poor light curve. According to the best-fitting model this star is the most luminous of our sample (\( \log(\frac{L}{L_\odot}) = 3.045 \) dex) and has an effective temperature of 5950 K. As for the radial velocity curve, the chosen value of the projection factor (1.27) provides a good match with the data and it is not significantly different from the value \( p = 1.33 \) obtained from the \( \chi^2 \) minimization with variable \( p \).

4.1.4 HV 12199

The best-fitting model for the Cepheid HV 12199 is shown in the bottom panels of Fig. 6. The luminosity derived from the fitting procedure (\( \log(\frac{L}{L_\odot}) = 2.91 \) dex) results to be the smallest in the selected sample and the effective temperature of this star is 6125 K. The model radial velocity curve, plotted in the right-hand panel, shows a small discrepancy in its amplitude with the data if we fix the value of the \( p \) factor to 1.27. It is necessary to decrease the projection.
factor to 1.17 in order to achieve the best match. It is interesting to note that, if we focus our attention only on the photometric data, the resulting best-fitting model for HV 12199 is given in the top panels of Fig. 6, with a predicted effective temperature and log \( \frac{L}{L_{\odot}} \) of 6200 K and 2.93 dex, respectively. However, we excluded this model because the radial velocity curve, obtained from the chosen value of the projection factor, has a too small amplitude to fit the data (see the solid line in Fig. 6). To account for the amplitude of the radial velocity data it would be necessary to decrease the projection factor to the too small value \( p \sim 1.0 \) (dashed line in the figure). This inconsistency that can be indeed due to a too high model effective temperature, led us to prefer the best model reported in Fig. 6.

4.1.5 HV 12198

Fig. 7 shows three possible models which describe the photometric and radial velocity data of HV 12198. The minimum \( \chi^2 \) for the photometry is obtained for the model at \( T_e = 6100 \) K and log \( \frac{L}{L_{\odot}} \) = 3.10 dex (bottom panel). However, this does not reproduce accurately the amplitude either of the \( U \)-band photometry or of the radial velocity data. Decreasing the parameter of the convection efficiency, \( \alpha_{\text{ml}} \), would produce the simultaneous increment of the amplitudes of both light and radial velocity curves. In this way we would recover the amplitudes of both the \( U \) band and the radial velocity curves, but we would decrease the accuracy of the fit in the remaining bands. As in the case of HV 12199, the radial velocity amplitude could be reproduced by decreasing the \( p \) factor to the barely acceptable value of \( \sim 1 \). If we exclude the \( U \) band, the model matching both the photometry and the radial velocity data is the one shown in the top panels of Fig. 7, corresponding to \( T_e = 6000 \) K and log \( \frac{L}{L_{\odot}} \) = 3.1. In this case we obtain an accurate fit of the radial velocity data with the chosen projection factor value, which decreases to 1.15 if we consider it as a free parameter in the \( \chi^2 \) minimization. On the basis of these results, we decided to consider as our best-fitting model for HV 12198 an intermediate case between those already described. It is shown in the central panel, includes the \( U \)-band fitting and provides a match of the radial velocity curve which is somewhat intermediate between those of the models in the top and bottom panels.
Figure 4. The same as Fig. 2 for V6.

Figure 5. The best-fitting model light curves and the model radial velocity curves (solid lines) for the Cepheid HV 12197 are matched with the data (empty squares), in the bottom and top panel, respectively. The plotted light curves are in the $B$, $V$, $I$ and $K$ bands from bottom to top. The best-fitting radial velocity curve obtained by varying the projection factor is shown as dashed line.
4.2 Comparison with the spectroscopic data

As a test for the accuracy of our procedure, we compared the effective temperature predicted by the best-fitting models for HV 12197 and HV 12199, with the results obtained by Mucciarelli et al. (2011) using an independent spectroscopic determination. The two panels of Fig. 8 show the model temperature as a function of the pulsational phase of the two quoted Cepheids and their spectroscopic temperatures, given by Mucciarelli et al. (2011) with a typical error bar of 100 K.

It is evident that models reproduce the spectroscopic data with great accuracy, thus further supporting the predictive capabilities of the adopted theoretical scenario, as well as of the model fitting technique.

4.3 Distance and reddening

Beyond the intrinsic stellar parameters of the best-fitting models (chemical composition, stellar mass, effective temperature, luminosity and convective efficiency parameter) and the corresponding projection factor, Table 2 reports the resulting distance moduli in all the observed bands, \( \mu_i \) (\( i = U, B, V, I, K \)), with the exception of HV 12197 for which the U-band data consist only of three measurements and are not used to infer the distance. The range of values we find for the apparent distance moduli of the selected stars can be at least in part understood in terms of differential reddening, but other effects might in principle be at work (see below). Using the obtained apparent distance moduli and the photometric band effective wavelengths, \( \lambda_i \), we fitted the Cardelli, Clayton & Mathis...
(1989) extinction law to derive simultaneously the absorption, $A_V$, and the true distance modulus, $\mu_0$, for the selected Cepheids. To this aim, we minimized the following $\chi^2$ function by varying the two unknown parameters:

$$\chi^2 = \sum_{i=1}^{N_{\text{bands}}} \left[ \mu_i - \left( a(x_i) + \frac{b(x_i)}{R_V} \right) A_V - \mu_0 \right],$$

where the total to selective extinction ratio is fixed to $R_V = 3.3$ (Feast & Walker 1987), $x_i = \frac{1}{\lambda_i}$ is the inverse of the $i$-band effective wavelength and the expressions for $a(x)$ and $b(x)$ are defined in Cardelli et al. (1989).

The results of the fit are shown in Fig. 9 and the best-fitting parameters are listed in Table 3. To be conservative, the errors on the individual band distance moduli include the rms of the fitting procedure and the error related to the selection of the best-fitting model summed in quadrature. Finally, the uncertainties on the parameters of the Cardelli fit have been derived from the $\chi^2$ confidence level at $1\sigma$. In the fitting procedure, we decided to exclude the $U$-band distance moduli of We 2 and V6 because they significantly deviate from the expected trend (see the filled triangles in Fig. 9).

3 Half the difference between the distance moduli obtained from the ‘secondary’ models defined above.
Inspection of Table 3 suggests colour excess estimates larger than the typically adopted value for NGC 1866, namely $E(B - V) = 0.06$ mag (Storm et al. 2005; Molinaro et al. 2012, and references therein), with the exception of the result for We 2. In fact, the resulting weighted mean value is $E(B - V) = 0.11 \pm 0.01$ mag, consistent with the result by Groenewegen & Salaris (2003), $E(B - V) = 0.12 \pm 0.02$ mag, as based on the simultaneous fit of the NGC 1866 Cepheid period–luminosity relation, in the $B$, $V$ and $I$ photometric bands.

As for the distance modulus of NGC 1866, a weighted mean of the obtained results for the five stars provides $\mu_0 = 18.56 \pm 0.03$ mag. Here, the uncertainty is only statistical but we are aware that several systematic effects are at work when reproducing observing quantities with pulsation models. First, we have to consider the effect of the adopted physical assumptions, namely the equation of state and the opacity tables. Previous theoretical investigations (Petroni et al. 2003; Valle et al. 2009) show that the effect of varying these ingredients is marginal and dominated by the effect of the model spatial resolution. The latter affects the predicted pulsation amplitudes and in turn the intrinsic parameters of the obtained best-fitting models. In particular, increasing the adopted spatial resolution by 10 mesh zones can imply a variation of about 100 K in the predicted effective temperature level. Another important source of uncertainty is the treatment of the pulsation and convection coupling. Even if we adopt a non-linear non-local time-dependent treatment of convection (see Stellingwerf 1982; Bono et al. 1999, for details), the equation system is closed by adopting a free parameter related to the mixing length. Variations of the mixing length affect the pulsation efficiency and amplitude. In particular, by varying the mixing length parameters by more than $\pm 0.05$ from the value reported in Table 2, we are not able to reproduce the observed curves, with resulting changes in the predicted luminosity levels smaller than $\pm 0.03$ dex. Obviously, this is only the effect of varying the mixing length parameter, but within the same turbulent convective model. Assuming a different treatment of convection might in principle produce larger errors even if we consider quite encouraging that the application of the model-fitting technique, from different groups (e.g. Bono et al. 2002; Keller & Wood 2002, 2006; Marconi & Clementini 2005; McNamara, Clementini & Marconi 2007) and using different approaches to the treatment of the pulsation–convection coupling, gives consistent results for the LMC distance modulus (Marconi & Clementini 2005; Marconi 2009). Finally, for what concern the light curves we have to consider the uncertainty on the adopted model atmosphere in transforming bolometric into $B$, $V$, $I$ and $K$ variations. According to our previous experience we know that theoretical predictions are dependent on the set of static atmosphere models adopted for transforming temperatures into colours. For example, changing the adopted model atmospheres from Castelli, Gratton & Kurucz (1997b, 1997a) to Kurucz (1993) produces colour effects of the order of 0.01 mag. In conclusion, to be conservative, we assume a systematic effect of $\pm 0.1$ mag on the inferred distance modulus, as due to all the above mentioned theoretical uncertainties. On this basis our final estimate of NGC 1866 distance modulus is $\mu_0 = 18.56 \pm 0.03$ (stat) $\pm 0.1$ (syst) mag.

This result is in agreement within the uncertainty interval with the value $18.51 \pm 0.03$ mag, obtained by Molinaro et al. (2012) from the Baade–Wesselink method, using the same $p$ factor adopted as reference value in this work. Their estimates of the distance to HV 12197, We 2 and HV 12198 are in excellent agreement with the values reported in Table 3. In particular, they found $18.63 \pm 0.12$, $18.54 \pm 0.09$ and $18.59 \pm 0.08$ mag for HV 12197, We 2 and HV 12198, respectively. For the remaining two stars, HV 12199 and V6, they found $18.62 \pm 0.10$ and $18.83 \pm 0.11$ mag, respectively, both systematically longer than our estimates, although consistent with them within the errors. In a recent work, using the infrared surface brightness method, Storm et al. (2011) obtained the distance for a sample of Cepheids in the LMC, including HV 12197, HV 12199 and HV12198, and their final value ($18.45 \pm 0.04$) is in agreement with our results within the errors. However, they used a period-dependent $p$ factor given by the equation $p = 1.550(\pm 0.04) - 0.186(\pm 0.06) \log P$. This is required to obtain distances to LMC Cepheids independent of their pulsation periods and distances to Galactic Cepheids in agreement with the HST parallaxes, with their surface brightness method (see Storm et al. 2011). As stated by the authors themselves, this relation is not easily reconciled with recent theoretical work (e.g. Nardetto et al. 2009) and provides $p$ factor values for short-period Cepheids (not less than 1.4), significantly larger than the results derived in the present study. This discrepancy could be due, at least in part, to limitations of our treatment of the coupling between pulsation and convection (see discussion above) but we have to note that the debate on the $p$ factor and on its possible dependence on the pulsation period is still open in the recent literature (see e.g. Ngeow et al. 2012, and references therein).

4.4 Mass–luminosity relation

The obtained stellar masses for the Cepheids in NGC 1866, as reported in Table 2, cover a range of values that might be the signature of differential mass loss. This occurrence is in agreement with previous findings by Brocato et al. (2004). Finally, we compared the derived masses and luminosities, as reported in Table 2, with an evolutionary MLR (Bono et al. 2000b), either neglecting or including mild overshooting according to the prescriptions by Chiosi, Wood & Capitanio (1993).

Fig. 10 clearly shows that the analysed Cepheids do not follow one of the two relations, but they are randomly placed at intermediate luminosities between those predicted by the canonical and the mild
overshooting MLRs, with the exception of the HV 12199 which results to be slightly more luminous than the mild overshooting prediction, although consistent with it within the uncertainties.

The fact that different luminosities are predicted for a given mass might suggest that the investigated Cepheid do not follow a MLR but are instead stochastically affected by some non-canonical phenomenon, likely a combination of mild overshooting and mass loss. However the application of the method to a larger sample of pulsators is needed in order to draw any reliable conclusion on the cause of the overluminosity distribution with respect to the canonical one.

5 CONCLUSIONS

We have used non-linear convective pulsation models computed by our team to reproduce the multifilter ($U$, $B$, $V$, $I$ and $K$) light and radial velocity curves of five classical Cepheids in NGC 1866, a young massive cluster of the LMC. The resulting best-fitting models give us information on the intrinsic stellar parameters and the individual distances of the investigated Cepheids. In the case of HV 12197 and HV 12199 the obtained effective temperature and its variation with the pulsation phase have been found to be in very good agreement with the spectroscopic determinations within their
and by the Mount Stromlo and Siding Spring Observatory, part of the Australian National University. We thank an anonymous referee for helpful comments and suggestions.

Table 3. Parameters obtained by fitting Cardelli extinction law: the Cepheids are listed in the first column, the second and third columns contain, respectively, the extinction, $A_V$, and the reddening, $(B-V)$, the intrinsic distance modulus, $\mu_0$, is in the last column.

| Name   | $A_V$ (mag) | $(B-V)$ (mag) | $\mu_0$ (mag) |
|--------|-------------|---------------|---------------|
| HV 12197 | 0.33 ± 0.07  | 0.10 ± 0.02   | 18.65 ± 0.06  |
| HV 12198 | 0.43 ± 0.07  | 0.13 ± 0.02   | 18.55 ± 0.05  |
| HV 12199 | 0.37 ± 0.07  | 0.11 ± 0.02   | 18.46 ± 0.06  |
| We 2    | 0.23 ± 0.10  | 0.07 ± 0.03   | 18.55 ± 0.08  |
| V6      | 0.46 ± 0.07  | 0.14 ± 0.02   | 18.57 ± 0.06  |

Figure 10. The masses and luminosities of the analysed Cepheids (empty squares) are compared with the canonical MLR (solid line) and with the mild overshooting MLR (dashed line).

... uncertainties. The masses and luminosities, obtained for all the five investigated pulsators, from this model-fitting technique satisfy a slightly brighter MLR than the canonical evolutionary one, indicating that non-canonical phenomena such as mild overshooting and/or mass loss are at work. As for the inferred distances, the individual values have been found to be consistent with each other within the uncertainties. Moreover, their weighted mean value corresponds to a distance modulus of 18.56 ± 0.02 (stat) ±0.02 (syst) mag, in agreement with several independent results in the literature. In particular the obtained result for the distance to NGC 1866 is in excellent agreement with the results obtained from the application of the model-fitting technique to LMC field Cepheids, RR Lyrae and δ Scuti variables (Bono et al. 2002; Marconi & Clementini 2005; McNamara et al. 2007).
