INTRODUCTION

The success of Neisseria gonorrhoeae (Gc) as a pathogen stems from the evolution of several sophisticated adaptation mechanisms that maintain its sole reservoir on the mucosae of infected humans. Some of these mechanisms are sex-specific and in the case of female infection, their evolution appears to be shaped by hormonal influences. Gc is also a genetically flexible pathogen that utilizes phase and antigenic variation to evade or capitalize upon host factors (Simms and Jerse, 2005) and the immunobiology of gonorrhea is both fascinating and puzzling due to the persistence of this organism during intense inflammation and the efficiency by which gonorrhea is transmitted to naïve and previously infected individuals (Sparling, 1999). Continued studies of the pathogenesis of this organism is therefore a rich field of investigation that can benefit from animal modeling to allow testing of hypotheses in the context of an intact host. Translational research is also needed to meet the pressing need for new prophylactic and therapeutic strategies against gonorrhea (Tapsall, 2009; Lewis, 2010).

Historically, animal modeling of gonorrhea has been challenged by several host restrictions. However, the use of estradiol-treated mice as surrogate hosts for Gc has partially fulfilled the need for an animal model of Gc genital tract infection. Here we describe the characteristics and limitations of experimental murine infection, the potential of transgenic mice to improve the mouse system, and information gained thus far on Gc adaptation to the female genital tract using this model. We also briefly discuss the use of this model in developing vaccines and vaginal microbicides against gonorrhea and describe a newly developed female mouse model of gonorrhea chlamydia coinfection for pathogenesis studies and developing products against pelvic inflammatory disease (PID).

ANIMAL MODELING OF GONOCOCCAL INFECTIONS

In the 1970s and 1980s, much effort was invested toward developing animal models of Gc infection. Genital tract infection was only successful in chimpanzees (Arko, 1989), which are no longer used for gonorrhea research due to their enormous cost and limited availability. Fortunately, a clue as to the role of the murine estrous cycle in inhibiting Gc colonization came from the discovery that female mice can be colonized when challenged during the proestrus stage of the estrous cycle. Gc is cleared upon transition into the postovulatory stages, and because the estrous cycle lasts only 4–6 days, Gc is recovered for only a few days (Streeter and Corbeil, 1981; Braude, 1982; Johnson et al., 1989). In 1990, Taylor-Robinson et al. (1990) described the use of 17β-estradiol to promote long-term colonization of germ-free BALB/c mice with Gc. Ten years later we confirmed Taylor-Robinson’s report and developed a protocol in which long-term Gc infection can be established in estradiol-treated BALB/c mice given antibiotics to suppress the overgrowth of commensal flora that occurs under the influence of estrogen (Jerse, 1999; Song et al., 2008; Figure 1A).

The susceptibility of rodents to human genital tract pathogens is often linked to the estrous cycle and the use of steroid hormones to promote susceptibility to Gc is consistent with other mouse models of sexually transmitted infections (STIs; Furr et al., 1989; Zeitlin
Gonorrhea mouse model

Characteristics of Murine Genital Tract Infection

Localization of Infection and Colonization Kinetics

Using the protocols we have described, Gc is recovered from the lower genital tracts of estradiol-treated BALB/c mice for an average of 12 days in a 14-day period and as long as 40 days when slow-release estradiol pellets are used, and for an average of 10 days when three injections of water-soluble estradiol are given (Jerse, 1999; Jerse et al., 2002; Song et al., 2008). Gc is localized in the vaginal lumen and within vaginal and cervical tissue, including the lamina propria (Song et al., 2008). Endometrial cultures are positive in 17–20% of mice (Jerse, 1999), a rate that is similar to that reported for ascended cervical infections in women (Hook and Holmes, 1985). This rate may be dose-dependent and actually higher based on the detection of Gc in endometrial tissue by confocal fluorescent microscopy (Imarai et al., 2008). Mouse-passaged strains are not required for murine infection and in early experiments, did not show an enhanced capacity to colonize (Jerse, 1999).

Following inoculation of BALB/c mice with 10^6 CFU of Gc strains FA1090 or MS11, the average number of Gc recovered from a single vaginal swab ranges from 10^7 to 10^8 CFU with most cultures yielding 10^7–10^8 CFU (Figure 1B; Jerse, 1999; Jerse et al., 2002; Soler-Garcia and Jerse, 2007; Song et al., 2008). Periods of dramatically reduced recovery or negative cultures are observed followed by a marked increase in recovery in 60–80% of BALB/c mice inoculated with Gc strains FA1090 or 1291 (Jerse, 1999; Simms and Jerse, 2006; and O. Jones-Nelson and Jerse, unpublished observations). We refer to these periods of reduced recovery as culture negative windows or the mid-phase of infection. (Jerse, 1999; Simms and Jerse, 2006) and have evidence that this pattern is hormonally regulated (Cole et al., 2010). It is critical that researchers who use this model be aware of fluctuations in colonization levels, particularly when measuring the effect of a particular host response on clearance or testing the efficacy of vaccines or therapeutic products. We obtain negative cultures for five consecutive days from mice that appear to have resolved infection before concluding infection has cleared. It is also important to understand that the estrous cycle will resume as the effects of the estradiol wear off, and mice will re-gain their natural resistance to infection upon transition into the luteal phase (Figure 1B). Additional doses of estradiol can be administered to prolong infection further.

Host Response to Infection

Gonorrhea in women is characterized by a mucopurulent cervical discharge with numerous PMNs or it can be asymptomatic with over 50% of women reporting no symptoms (Hook and Holmes,
Approximately 50% of infected BALB/c mice (range 30–80%) have a higher percentage of PMNs in stained vaginal smears on days 4–5 compared to uninfected control mice (Jerse, 1999; Jerse et al., 2002; Soler-Garcia and Jerse, 2007; Packiam et al., 2010), and significantly more PMNs are detected within vaginal and cervical tissue from infected mice on days 2 and 5 post-inoculation (Song et al., 2008). Localized production of proinflammatory cytokines and chemokines IL-6, TNF-α, KC, and MIP-2 is significantly increased on day 5 of infection, with MIP-2 expression positively correlating with PMN influx (Packiam et al., 2010; Figure 1B).

Mouse strain differences in susceptibility and host response have been documented. Like BALB/c mice, estradiol-treated CD1, SLC::ddY (Jerse, 1999), and C57BL/6 mice are susceptible to infection. Interestingly, Gc do not elicit an innate inflammatory response in C57BL/6 mice despite being colonized to similar levels as BALB/c mice (Packiam et al., 2010). C57BL/6 mice therefore appear to mimic asymptomatic infection and perhaps can be used to better define the pathways that lead to or suppress the inflammatory response to Gc. Known differences between C57BL/6 and BALB/c mice include the absence of phospholipase A2 in C57BL/6 mice (Kennedy et al., 1995), which may play a role in generating lipid mediators (Kudo and Murakami, 2002) and inducing pro-inflammatory cytokines and chemokines (Granata et al., 2005). Interestingly, estradiol-treated C3H/HeN mice are resistant to Gc (Packiam et al., 2010) and untreated C3H/HeN mice are also less susceptible to transient Gc colonization following intrauterine inoculation (Streeter and Corbeil, 1981). The natural resistance-associated macrophage protein (Nramp1) is responsible for the resistance of C3H/HeN mice against pathogens that are highly adapted for life within macrophages (Forbes and Gros, 2001). The impact of Nramp1 on susceptibility to Gc infection is not known.

A significant advance in understanding the immune response to Gc was made recently by Mike Russell’s laboratory who showed Gc induces IL-17 responses and that secretion of IL-6, IL17, and MIP-2α is dependent on IL-17 receptor signaling. Importantly, inhibition of IL-17-induced responses in mice via antibody-mediated depletion of IL-17 or infection of IL-17 receptor knock-out mice resulted in increased recovery of bacteria and a significantly longer duration of infection compared to control mice (Feinen et al., 2010). The relevance of this finding to IL-17 responses in humans is supported by the recent report that levels of serum IL-17A and IL-23, which plays a role in the differentiation and proliferation of Th-17 cells, were elevated in patients with Gc urethritis or pharyngitis compared to healthy control subjects (Gagliardi et al., 2011). IL-17, along with IL-22, play a role in inducing antimicrobial peptides in epithelial cells (Kolls et al., 2008). Evidence that Gc induces IL-17 via endotoxin-mediated signaling through toll-like receptor 4 (TLR4; Feinen et al., 2010) may therefore provide a new angle for the design of preventive therapies.

There are many unresolved questions regarding the adaptive humoral response to Gc, which is not protective in humans and appears to be immunosuppressed. While there is some evidence of protective immunity in individuals with repeated exposure, humans can be reinfected with the same strain or serovar and antibody titers are not remarkable and decline over time (Sparling, 1999; Russell and Hook, 2008). Mice also develop a transient and insignificant humoral response to infection and there was no evidence of a humoral memory response or reduced infection in mice that were previously infected with the same strain compared to naïve age-matched, estradiol-treated control mice (Song et al., 2008). Imarai et al. (2008) investigated the basis for the lack of a humoral response to Gc using the mouse system. Gc were detected in endometrial tissue from estradiol-treated BALB/c mice for as long as 22 days and importantly, significantly higher numbers of TGF-β1+ CD4+ T cells and a subset of CD4+ CD25+ Foxp3+ T cells were detected in the regional lymph nodes of infected mice compared to control mice. Increased infiltration of TGF-β1+ CD11b+ macrophages into the genital tracts of infected mice also occurred, which could favor the differentiation of T regulatory cells, and thereby suppress immune responses against Gc (Imarai et al., 2008).

LIMITATIONS OF USING MICE TO STUDY GONOCOCCAL INFECTIONS

GENITAL TRACT PHYSIOLOGY

Several similarities and differences exist between the lower genital tracts of female mice and women. Similar factors include reduced O2 tension, the presence of glucose and lactate (Exley et al., 2007), and cytokine monophosphate N-acetylneuraminic acid (CMP-NA; Wu and Jerse, 2006) used to sialylate the Gc surface during infection. The average vaginal pH of estradiol-treated female mice is pH 6.6 (range 5.8–7.2; Muench et al., 2009). This pH is higher than human vaginal pH (average pH 3.5–4.5) but similar to human cervical pH [proliferative stage, average 6.8 (5.5–8.0); secretory stage, average 6.1 (range 5.1–8.4)] (Singer, 1975), which is the primary site of infection in women. Hormonally driven changes in mucus viscosity, commensal flora (Braude, 1982), and histology (Corbeil et al., 1985) are similar to that which occurs in the human reproductive cycle. A major difference is the fact that there is no period of menstrual bleeding in mice that brings proteases, hemoglobin, and other serum factors into the reproductive tract. Fewer anaerobes colonize the murine genital tract compared to the normal microbiota of most women of reproductive age (Noguchi et al., 2003), but Gram-positive and Gram-negative facultatively anaerobic flora are present. The use of antibiotics to reduce potentially inhibitory commensal flora in the protocols we have described eliminates bacteria of the Enterobacteriaceae and Pseudomonas families and most Gram-positive flora. Some mice remain colonized with Gram-positive organisms, particularly when vancomycin is not used, and vaginal lactobacilli are frequently isolated (Jerse et al., 2002).

HOST RESTRICTIONS AND TRANSGENIC MICE

Colonization receptors

Gc expresses several ligands that bind to specific receptors to mediate adherence or uptake by epithelial cells. At least three of these receptors are host-restricted. Colonization pili are expressed by the vast majority of human isolates (Kellogg et al., 1963); in contrast, murine vaginal isolates lose the piliated colony morphology over time (Jerse, 1999). Mice probably lack the pilus colonization receptor, although its identity is unresolved. Human membrane cofactor protein (CD46) is hypothesized by some to serve as the neisserial pilus receptor (Kallstrom et al., 1997, 2001) and the demonstration that pilus-mediated interactions with CD46 trigger cellular responses through Src kinase-dependent phosphorylation (Lee et al., 2002; Weyand et al., 2009) suggests CD46 has an immunoregulatory role during infection. CD46+ transgenic mice support
meningococcal dissemination to the brain following intranasal or intraperitoneal inoculation and induce higher levels of cytokines (Johansson et al., 2003, 2005). The impact of CD46 expression on Gc infection of mice has not been reported.

The human CR3 (hCR3) integrin is utilized by Gc to invade primary cervical cells via the binding of pili, LOS, and iC3b (Edwards et al., 2002). The hCR3 molecule has a high degree of similarity to murine CR3; however, it appears to be host-restricted based on studies with an hCR3-specific monoclonal antibody that blocks Gc invasion of human cells (unpublished data in collaboration with Drs. Jennifer Edwards and Michael Apicella). Additionally, Rice and colleagues recently showed human factor H (fH), which is host-restricted (Ngampasutadol et al., 2008a), bridges the interaction between the gonococcus and CR3 (Agarwal et al., 2010). Therefore a transgenic mouse model that reproduces this invasion pathway may require the expression of both hCR3 and fH.

Other host-restricted receptors known to be used by Gc to invade epithelial cells include the human carcinoembryonic antigen collagen adherence molecules (CEACAMs) -1, -5 and -6 to which the phase variable opacity (Opa) proteins bind and CEACAM-3, through which Opa-mediated uptake by PMNs occurs in the absence of opsonization. Opa–CEACAM-1 binding causes immunosuppression of T cells and killing of B cells (Sadarangani et al., 2011). CEACAM transgenic mice are available (Eades-Perner et al., 1994; Bhattacharya-Chatterjee et al., 2008) and CEACAM-5 transgenic mice were recently used by Christof Hauck’s laboratory to demonstrate a novel role for Opa–CEACAM interactions in preventing detachment of infected epithelial cells via enhancement of integrin-mediated cell to cell adhesion and cellular adhesion to extracellular matrix. CEACAM-5 transgenic mice had a higher colonization load than normal mice 1 day after inoculation. This findings supports the interesting hypothesis by this group that CEACAM-engaging bacteria subvert shedding from mucosal surfaces (Muenzner et al., 2005, 2010). Additional studies with CEACAM transgenic mice are needed to demonstrate the Opa–CEACAM invasion pathway during female genital tract infection and test the role of Opa proteins as immunosuppressive factors in vivo. Also, the importance of Opa–CEACAM-3 mediated uptake by PMNs relative to opsonic uptake during cervical infections, where complement is present in the absence of inflammation, is an interesting question that could potentially be addressed using complement depletion of CEACAM-3 transgenic mice.

Gc that express the lacto-N-neotetraose (LNT) species of LOS invade through the asialoglycoprotein receptor of primary urethral cells from men. This pathway is sex-specific (Edwards and Apicella, 2004) and thus unlikely relevant to animal modeling of female infections. Other less characterized adhesins and invasins have been described including OmpA, which mediates invasion of immortalized human endocervical and endometrial cells. Interestingly, an ompA mutant was attenuated for murine infection. OmpA was also required for uptake or survival within cultured murine macrophages and whether the observed attenuation in vivo was due to a colonization versus survival advantage is not known (Serino et al., 2007). P1A strains undergo porin-mediated invasion through Gp96 and scavenger receptor SREC. This pathway is phosphate-dependent and not restricted to human cells (van Putten et al., 1998; Kuhlewein et al., 2006; Rechner et al., 2007). Gc also invades human cervical cells that do not express CEACAMs (Swanson et al., 2001) and Opa variants are more invasive than Opa variants in some systems (Song et al., 2000). The identification of bacterial ligands and receptors used during murine infection is handicapped by the lack of immortalized murine cervical or endometrial cell lines. Adherence and invasion pathway(s) exist for murine infection based on the visualization of Gc associated with genital tract cells (Jerse, 1999) and within mouse tissue (Song et al., 2008) and the detection of intracellular Gc in endometrial cells from murine uterine explant cultures (Imarai et al., 2008).

Iron-binding glycoproteins
The capacity of Gc to obtain iron from transferrin (Tf) and lactoferrin (Lf) through specific receptors is also host-restricted (Lee and Schryvers, 1988). Expression of either the Tf or Lf receptor was critical for urethral infection of male subjects (Cornelissen et al., 1998; Anderson et al., 2003), but the absence of these receptors or the hemoglobin receptor, which is not host-restricted (Stojilkovic et al., 1996) does not confer a growth disadvantage in estradiol-treated mice (Jerse et al., 2002). Usable iron sources in the female genital tract include siderophores produced by commensal flora (Mickelsen et al., 1982; Carsons et al., 1999; Strange et al., 2010), hemin, and ferritin from dying epithelial cells, which are rapidly turned over during the course of the reproductive cycle (Schryvers and Stojilkovic, 1999), and iron complexed to citric acid, oxalic acid, pyrophosphate, nitritolriacetate, or other metabolites (Mickelsen et al., 1982). Additionally, iron is likely to be more soluble in the lower pH and reduced O2 tension of the female genital tract and thus more available to Gc. A transgenic hTf mouse strain was recently used as an improved model of N. meningitidis septicemia from which meningococci were recovered for a longer period and at a 100-fold higher concentration compared to wild type mice (Zarantonelli et al., 2007). The use of hTf transgenic mice may also significantly increase Gc genital tract colonization and perhaps support Gc infection of other body sites. However, the capacity of Gc to replicate in normal mice is direct evidence that non-host-restricted iron stores exist in the female lower genital tract.

Complement regulatory proteins
Gc that show inherently high levels of porin-mediated resistance to normal human serum bind the soluble regulatory proteins C4b-binding protein (C4BP; Ram et al., 2001) and factor H (for strains of the P1A serotype; Ram et al., 1998) to down-regulate the classical and alternative pathways, respectively. Rice and colleagues showed that only human or chimpanzee FH and C4BP bind serum resistant strains, and the generation of hC4BP and/or hfH transgenic mice therefore holds promise for testing the importance of porin-mediated serum resistance during female genital tract infection (Ngampasutadol et al., 2008b). Due to the role that complement activation plays in inducing cytokines and chemokines and the adaptive response (Dunkelberger and Song, 2010) such mice would also be a valuable resource for studying the host response to infection.

IgA1
Like many human-specific mucosal pathogens, Gc produces an IgA1 protease that cleaves only primate IgA1 (Qiu et al., 1996). How important IgA1 protease is for infection is not known. Russell and
colleagues found no evidence of IgA cleavage products in cervical fluid from women with gonorrhea (Hedges et al., 1998), and IgA2 presumably can serve as a redundant protective factor. An IgA1 protease mutant was not attenuated for urethral infection of naïve male volunteers (Johannsen et al., 1999), although its importance in previously infected subjects cannot be ruled out. Attenuation of an IgA1 protease mutant of Streptococcus pneumoniae in a mouse septicemia model (Polissi et al., 1998) suggests non-host-restricted roles exist for this class of enzymes. Gc IgA1 protease cleaves a phagosomal maturation protein to promote increased survival and transit through polarized epithelial cells (Lin et al., 1997; Hopper et al., 2000) and may modulate the host response based on the reported inhibition of apoptosis of immune cells and induction of proinflammatory cytokines by purified IgA1 protease in vitro (Lorenzen et al., 1999; Beck and Meyer, 2000). Whether these interactions are host-restricted has not been reported.

**PATHOGENESIS STUDIES**

Gc encounters a variety of innate defenses in the female genital tract, some of which are illustrated in Figure 2A. The testing of bacterial mutants in factors that are hypothesized to promote Gc survival in vivo has confirmed predictions from in vitro studies and generated new information that may be relevant to lower genital tract infection in women, particularly with regard to evasion of phagocytes, antimicrobial peptides, and commensal bacteria and adaptation to hormonally regulated factors (Figure 2B).

### SIALYLTRANSFERASE BUT NOT ANTI-OXIDANT FACTORS PROTECT AGAINST PMNS

Gc is superbly adapted for evasion PMNs in which they survive and perhaps replicate (Casey et al., 1979; Simons et al., 2005; Criss et al., 2009). Examination of PMN killing mechanisms in the mouse system has the advantage of reproducing natural pathways of PMN recruitment and activation and physiologically relevant concentrations of iron, oxygen, and glucose needed to fuel the oxidative burst (Storz et al., 1990) and CMP-NANA, which when added to gonococcal LNT LOS via the action of α-2,3-sialyltransferase (Lst), increases resistance to complement-mediated uptake by PMNs (Smith et al., 1995; Gill et al., 1996). Additionally, PMNs from estradiol-treated mice produce a dose-dependent oxidative burst when exposed to Gc that is primarily intracellular (Soler-Garcia and Jerse, 2007) as reported for human PMNs (Noids and Rest, 1991; Simons et al., 2005). Limitations include differences in the concentrations of myeloperoxidase and other granular enzymes.
in murine and human PMNs (Rausch and Moore, 1975), and the absence of Opa–CEACAM-mediated uptake by PMNs. Although it is possible that estradiol impairs PMN killing, we detect no difference in the killing capacity of PMNs from estradiol-treated versus untreated mice (Soler-Garcia and Jerse, 2007).

There is now much evidence that the oxidative burst of phagocytes does not challenge Gc, including studies with PMNs from humans with chronic granulomatous disease and the use of pharmacological inhibitors of the respiratory burst (Rest et al., 1982; Criss et al., 2009). Infection studies in C57BL/6 mice that have a defective NADPH oxidase (Phox) provided in vivo evidence that phagocytic-derived ROS do not challenge Gc during genital tract infection (Wu and Jerse, 2006) with the caveat that C57BL/6 mice do not produce a significant PMN response to Gc infection (Packiam et al., 2010). Whether this host defense is more potent in body sites where oxygen levels are higher such as the pharynx, is not known, but seems unlikely based on PMN killing assays performed under anaerobic versus aerobic conditions (Casey et al., 1986; Frangipane and Rest, 1992).

Perhaps a bigger question is how Gc evades phagocyte-derived ROS. Gc is equipped with a battery of factors that protect it from in vitro exposure to H₂O₂ and inducers of intracellular and extracellular ROS, including the detoxifying enzymes catalase (Kat) and cytochrome C peroxidase (CcP), non-enzymatic quenching of cellular ROS, including the detoxifying enzymes catalase (Kat) and cytochrome C peroxidase (CcP), non-enzymatic quenching of O₂•⁻ by Mn⁺⁺, which is taken up by the manganese transporter MntABC, methionine sulfoxide reductase (MsrAB), which repairs oxidatively damaged proteins, a thiol-disulfide oxidoreductase (Sco), azurin, bacterioferritin and novel peroxidase-induced genes of unknown function (Seib et al., 2006). This abundance of anti-oxidant mechanisms is impressive, yet there is no evidence that these factors protect Gc from the vigorous PMN response encountered in vivo. For example, a kat mutant and kat ccp and kat sco mutants of strain 1291 were not more susceptible to killing by human PMNs (Seib et al., 2005). Similarly, single, double, and triple mutants in the kat, ccp, msrAB, and mntC genes in strain MS11 were not more susceptible to killing by murine PMNs. These mutants were also not attenuated during infection of normal BALB/c mice or Phox-deficient and Phox-sufficient C57BL/6 mice (Wu et al., 2009). Further genetic stripping of the factors known to protect Gc from exposure to H₂O₂ or inducers of ROS may debilitate Gc against O₂•⁻-dependent PMN killing. The answer may, however, reside in novel mechanisms that do not involve direct protection from ROS (Lorenzen et al., 2000; Criss and Seifert, 2008; Criss et al., 2009).

Possible new functions for MsrA and MntC were revealed using murine infection. The msrA mutant showed delayed attenuation in vivo in BALB/c mice and because macrophages appear later than PMNs during infection of BALB/c mice (Song et al., 2008) reduced recovery of msrA mutant may be due to increased sensitivity to macrophage killing as described for other bacteria (St John et al., 2001; Douglas et al., 2004). Additionally, inactivation of mntC resulted in an attenuated phenotype in normal BALB/c and Phox-deficient and Phox-sufficient C57BL/6 mice. MntC-deficient Gc may be more susceptible to ROS produced by epithelial cells. Inactivation of mntC may also reduce biofilms, which may be important in stabilizing colonization (Lim et al., 2008).

In contrast to the anti-oxidant factors tested above, Lst plays a detectable role in defending Gc from PMN killing in vitro and in the mouse model. Sialylation of Gc occurs within the first day of murine infection and inactivation of the lst gene confers a survival disadvantage in BALB/c mice. Decreased resistance to PMN killing is the most likely explanation for the observed attenuation based on the greater susceptibility of the lst mutant to opsonophagocytic uptake and killing by murine PMNs in vitro and significantly faster clearance of the lst mutant following intraperitoneal injection compared to sialylated, wildtype bacteria (Wu and Jerse, 2006). Lst also increases resistance to complement-mediated bacteriolysis by enhancing the binding of fH to P1B porin (Madico et al., 2007). The importance of sialyltransferase in Gc survival is therefore likely underestimated in studies with normal mice due the host restriction for fH. While the host restriction for fH did not affect opsonophagocytosis at a functionally detectable level in our study, the lst mutant was equally attenuated in normal and C5-deficient mice (Wu and Jerse, 2006). These findings are consistent with the requirement for higher numbers of membrane attack complexes for bacteriolysis than opsonins for phagocytosis. Again, studies in fH transgenic mice could further illustrate the importance of sialylation in infection.

EVIDENCE OF COMPLEX INTERACTIONS BETWEEN GC AND LACTOBACILLI

Epidemiological data show an increased risk for gonorrhea in women that lack vaginal lactobacilli, with some studies implicating H₂O₂-producing lactobacilli as a defense in particular (Antonio et al., 1999; Wiesenfeld et al., 2003) and others showing the same association regardless of the H₂O₂ production phenotype (Saigh et al., 1978; Hillier et al., 1992; Martin et al., 1999). It is not clear whether lactobacilli are directly responsible for the inverse correlation between gonorrhea and vaginal lactobacilli because an absence of lactobacilli is associated with bacterial vaginosis in which an imbalance of other bacteria also occurs (Hillier et al., 1992). H₂O₂-producing Lactobacillus sp. inhibit Gc in vitro (Saigh et al., 1978; St Amant et al., 2002), and Gc kat and ccp mutants are more susceptible than wild type Gc. However, surprisingly, there was no difference in the recovery of wild type, kat, or kat ccp mutant Gc from mice that were pre-colonized with H₂O₂-producing L. crispatus compared to mice that were not colonized with this human commensal (Muench et al., 2009). L. crispatus makes several factors that could enhance Gc growth or survival, one of which is lactate (Smith et al., 2007). As inactivation of the gonococcal lactate permease (lctP) gene was attenuating for murine infection (Exley et al., 2007), we hypothesized that utilization of Lactobacillus-produced lactate might balance the detrimental effects caused by Lactobacillus-produced H₂O₂ in vivo. However, a kat lctP Gc mutant also colonized mice with L. crispatus as well as mice without L. crispatus (Muench et al., 2009).

The murine infection data predict that vaginal H₂O₂-producing lactobacilli do protect against Gc, possibly because the O₂•⁻ tension may not be sufficient for adequate H₂O₂ production. However, it is possible that H₂O₂ is more stable in the lower pH of the human vagina or the colonization density of L. crispatus in mice is not sufficiently high. A recent report that human cervical secretions block H₂O₂-mediated bactericidal activity however, also suggests Lactobacillus-derived H₂O₂ is not a formidable defense against STI pathogens (O’Hanlon et al., 2010). These studies do not rule out a role for other Lactobacillus factors in challenging N. gonorrhoeae (Sperbeck and Arvidson, 2010). Such factors may have also been produced by non-H₂O₂ producing murine lactobacilli in control
mice in the mouse study discussed above. Nonetheless, interesting observations have been made while working with the mouse model in our laboratory that suggest Gc has evolved mechanisms to coexist with these commensals. For example, L. murinus, a mouse Laclobacillus sp., supports growth of Gc on solid agar (Jerse et al., 2002) as do H2O2-producing human L. murinus, a mouse model in our laboratory that suggest Gc has evolved mechanisms to ing observations have been made while working with the mouse mice in the mouse study discussed above. Nonetheless, interest-tested thus far in the mouse model, which is consistent with a role MtrCDE-deficient mutants are the most attenuated of all mutants related antimicrobial peptide (CRAMP), progesterone, and fatty acids (Shafer et al., 2001; Jerse et al., 2003; Warner et al., 2008). MtrCDE-deficient mutants are the most attenuated of all mutants tested thus far in the mouse model, which is consistent with a role for this efflux system in protecting against host defenses (Jerse et al., 2003). Inactivation of MtrR and MtrA, which negatively and positively regulate mtrCDE expression, respectively causes a phenotype in mice that is consistent with the importance of the MtrC–MtrD–MtrE efflux pump in infection (Warner et al., 2007). In contrast, the FarA–FarB–MtrE efflux pump system does not have a detectable role in murine infection (Jerse et al., 2003). This system primarily protects Gc from long chain fecal lipids, and thus may be more important during rectal infections (Lee and Shafer, 1999). Infection studies in mice that are deficient in CRAMP (Nizet et al., 2001) may facilitate further investigation of the role of the MtrC–MtrD–MtrE pump in infection; however, the presence of more than one pump substrate may complicate definitive identification of host factors that challenge MtrCDE-deficient Gc in vivo. mtrE mutants are also more sensitive to bactericidal/permeability-increasing (BPI) protein (A. A. Begum and A. E. Jerse, unpublished data), which is a lipid A-binding protein that is present in both the human and murine genital tracts (Canny et al., 2006; Eckert et al., 2006). Also, increased susceptibility of MtrCDE-deficient Gc to progesterone in vitro and the faster clearance of MtrCDE-deficient Gc from normal mice versus ovariec-tomized mice suggests progesterone or progesterone-regulated factors challenge these mutants during infection.

Derepression of the mtrCDE operon through a single base pair deletion in the mtrR promoter region or point mutations in the MtrR structural gene is a mechanism by which Gc strains become resistant to macrolide antibiotics and high levels of penicillin (Shafer et al., 2001). Antibiotic resistance mutations often confer reduced fitness in vitro due to the effect these mutations have on growth. An exception to this paradigm are mtrR locus mutations that confer increased fitness in the mouse model. Commonly isolated mtrR locus mutations confer different levels mtrCDE derepression, which is mirrored by different levels of fitness advantage in vivo (Warner et al., 2008). One might predict that the percentage of mtrR locus mutants would be higher among clinical isolates should the observed fitness benefit in mice hold true for human infection. It may be that the mouse data are not predictive of events during human infection or there are sex-based or anatomical differences in the types of innate effectors that select for mtrR locus mutations. Alternatively, mtrR locus mutants frequently carry more than one antibiotic resistance mutation, which may confer an overall fitness cost (Komp Lindgren et al., 2005).

ADAPTATION TO HORMONALLY REGULATED FACTORS THROUGH OPA GENE PHASE VARIATION

The neisserial Opa proteins are a family of phase variable outer membrane proteins that are encoded by 10–12 unlinked genes (Simms and Jerse, 2005). Selection for Opa expression during urethral infection occurs in naturally (James and Swanson, 1978) and experimentally infected male volunteers (Swanson et al., 1988; Jerse et al., 1994). Selection for Opa variants in the female genital tract appears more complex, with predominantly opaque (Opa+) colonies isolated during the proliferative stage of the menstrual cycle and transparent (Opa−) colonies isolated during or shortly after menses. Based on this intriguing observation, James and Swanson (1978) hypothesized that subpopulations of bacteria are better adapted for different stages of the reproductive cycle. This hypothesis is consistent with reported higher rates of positive cultures from women with gonorrhea during the proliferative stage than the middle secretory stage (Koch, 1947; Johnson et al., 1969; James and Swanson, 1978; McCormack and Reynolds, 1982; Figure 3A).

Interestingly, Opa+ variants are isolated from BALB/c mice in a cyclical recovery pattern that consists of early (Opa+), mid (Opa−) and late (Opa+) phases. Consistent with subpopulations of bacteria being cleared or having an advantage, fluctuations in the predominant Opa phenotype recovered are paralleled by changes in the total number of Gc recovered (Simms and Jerse, 2006; Figure 3B). A cyclical recovery pattern also occurs during short-term colonization of mice that are not treated with estradiol. The importance of Opa proteins during the early and late phases was confirmed by the demonstration that an Opa-deficient mutant colonized mice less well than the mutant expressing one functional opa allele during the first day of infection, and unlike the Opa-deficient strain, the Opa+ strain was recovered following the mid-phase (Cole et al., 2010). A link between the reproductive cycle and the cyclical recovery pattern was revealed by studies with ovariec-tomized mice, which select for Opa- variants early in infection and maintain this selection over time. Also, unlike intact (normal) mice, fluctuations in the number of Gc recovered from ovariec-tomized mice were not observed (Cole et al., 2010). The selective forces responsible for the cyclical changes in Op gene- notype in normal mice must be due to a CEACAM-independent Opa function. Complement was shown to preferentially kill Opa+ variants of strain MS11 (Dos et al., 1997) and complement levels in the female human and murine genital tracts are hormonally regulated (Hasty et al., 1994; Li et al., 2002). However, experiments with complement-depleted mice did not support complement as the selective factor (Cole et al., 2010).

The factors that select for Opa+ variants during human infections are also not known. In women, CEACAM-mediated adherence to and invasion of cervical cells may select for Opa-expressing variants during infection, as may increased attachment of epithelial cells with adherent bacteria (Muenzner et al., 2005, 2010) as discussed. Based on data from BALB/c mice, we hypothesize that CEACAM-independent factors also exist. CEACAMs were not detected on
Alarmingly, the reliance on antibiotic treatment as a control measure is seriously threatened by the rapid emergence of antibiotic-resistant strains (Tapsall et al., 2005). The need for an animal model to facilitate pre-clinical testing of products against gonorrhea was reflected by the numerous academic and industrial collaborators who approached our laboratory upon the first publication of the mouse model. Continued research in this area is critical. Here we briefly describe our experience with testing vaccines and vaginal microbicides in the mouse model with an emphasis on practical considerations and challenges for product development.

Vaccine development

Successful development of a gonorrhea vaccine faces many challenges as recently reviewed (Zhu et al., 2011). The availability of an animal model for systematic testing of different antigens, immunization strategies, and defining correlates of protection should facilitate vaccine development as should growing information on protective immunological pathways in mice and humans (Imarai et al., 2008; Feinen et al., 2010; Gagliardi et al., 2011). An OMV-based vaccine demonstrated protection against strain MS11 (Plante et al., 2000) but was not successful in subsequent studies or with other strains (Zhu et al., 2011). As of yet, vaccine-induced protection of mice with other antigens has not been reported, although data we have obtained thus far are useful for evaluating the effectiveness of different immunization strategies in inducing local and systemic immune responses. A practical obstacle for vaccine studies

FUTURE DIRECTIONS

PRODUCT DEVELOPMENT

Safe and effective therapeutic and prophylactic products against Gc are greatly needed to reduce the incidence of gonorrhea and protect women's reproductive health. Infertility treatment is a significant and hidden cost of ascended infections and ectopic pregnancy causes 4.1% of maternal-related deaths in industrialized countries (Khan et al., 2006). Gonorrhea is also a cofactor for HIV transmission (Cohen et al., 1997). Alarmingly, the reliance on antibiotic treatment as a control measure is seriously threatened by the rapid emergence of antibiotic-resistant strains (Tapsall et al., 2005). The need for an animal model to facilitate pre-clinical testing of products against gonorrhea was reflected by the numerous academic and industrial collaborators who approached our laboratory upon the first publication of the mouse model. Continued research in this area is critical. Here we briefly describe our experience with testing vaccines and vaginal microbicides in the mouse model with an emphasis on practical considerations and challenges for product development.

Vaccine development

Successful development of a gonorrhea vaccine faces many challenges as recently reviewed (Zhu et al., 2011). The availability of an animal model for systematic testing of different antigens, immunization strategies, and defining correlates of protection should facilitate vaccine development as should growing information on protective immunological pathways in mice and humans (Imarai et al., 2008; Feinen et al., 2010; Gagliardi et al., 2011). An OMV-based vaccine demonstrated protection against strain MS11 (Plante et al., 2000) but was not successful in subsequent studies or with other strains (Zhu et al., 2011). As of yet, vaccine-induced protection of mice with other antigens has not been reported, although data we have obtained thus far are useful for evaluating the effectiveness of different immunization strategies in inducing local and systemic immune responses. A practical obstacle for vaccine studies
in the estradiol-treated mouse model is the need to immunize more mice than are actually challenged since only diestrus or anestrus stage mice can be used in the challenge phase of the experiment. Ovariectomized mice can be used to circumvent this problem since they do not need to be staged prior to estradiol treatment. Ovariectomized mice are more expensive, however, and we speculate that their innate responses may be compromised based on the absence of the cyclical recovery pattern in ovariectomized mice as discussed (Cole et al., 2010). Certain host restrictions should especially be considered when testing vaccines for humans. IgA1 protease and restrictions in the complement cascade may most significantly challenge the power of murine infection to predict vaccine efficacy, particularly against serum resistant strains. The development of hC4BP and fH transgenic mice should therefore be a useful tool for vaccine testing (Ngampasutadol et al., 2008b). Passive delivery of purified fH or hC4BP could also be used as was recently shown to improve experimental infection of rats by N. meningitidis (Granoff et al., 2009).

Vaginal microbicides
The development of topically applied products for reducing the risk of STIs in women has been a public health priority in recent years. Topical agents that have been tested against Gc and C. trachomatis in the estradiol-treated mouse model include porphyrin binding proteins (Bozja et al., 2004), formulated natural, and synthetic sulfated and sulfonated polymers [CarraGuard™, Ushercell, T-PSS, PRO 2000™], acid-buffering agents [ACIDFORM, BufferGel™], and cellulose acetate phthalate (CAP; Spencer et al., 2004). With the exception of CarraGuard, there was good correlation between the in vitro activity of each agent and effectiveness in vivo. Interestingly, CarraGuard prevented infection of mice but did not inhibit Gc in vitro (Spencer et al., 2004). This finding underscores the importance of testing products in an animal model system. Several of these products have since undergone safety and acceptability testing in humans (Carraguard, 2010; von Mollendorf et al., 2010).

Many challenges face the assessment of vaginal microbicide effectiveness in humans (Ramjee et al., 2010), but animal modeling can continue to play useful role in the development of these products for screening novel compounds and expanding testing protocols to include the assessment of repeated application of agents, which can affect susceptibility (Cone et al., 2006). A limitation of the gonorrhea mouse model, like most STI models, is that it is not a transmission model and the bacterial suspension used to inoculate mice does not simulate the bodily fluids that transmit the microbe in terms of pH, biochemical make-up, and the presence of immune effectors and inhibitors of host defenses.

ANIMAL MODELING OF COINFECTIONS
An important characteristic of STIs is the frequency by which more than one pathogen is present. The availability of well-characterized models of gonorrhea (Song et al., 2008), chlamydia (Darville et al., 2003), and M. genitalium (McGowin et al., 2009) infection affords the opportunity to develop coinfection models for these three pathogens, which are major causes of PID. As many as 70% of individuals with gonorrhea have chlamydia (Miller et al., 2004) and we recently developed a gonorrhea chlamydia coinfection model for use as a research tool (Vonck et al., 2011). Significantly more vaginal PMNs were detected in coinfected mice compared to mice infected with either pathogen alone. This result is consistent with the reported higher levels of symptoms in individuals coinfected with Gc and C. trachomatis (Nsuami et al., 2004; Rosenvinge and Lau, 2009). Interestingly, higher numbers of Gc were recovered from coinfectected mice compared to mice infected with Gc alone (Vonck et al., 2011). Continued use of the gonorrhea chlamydia coinfection model combined with human-based systems should illuminate the basis for these observations. The development of dually active therapeutic agents should also be accelerated by this model. Such agents are needed to simplify treatment regimens and potentially reduce the costs associated with therapy.

SUMMARY
The development of the estradiol-treated mouse model of Gc infection has expanded the research tools available for studying Gc genital tract infections. Researchers can now experimentally manipulate the host response and utilize mice that are genetically defective in immunological pathways and effector molecules to inform our understanding of the host response against gonorrhea, as has benefitted the study of many other infectious diseases. The growing availability of transgenic mice should improve the relevance of mice as surrogate hosts for Gc and provide an opportunity to test the biological significance of host-restricted bacterial-host cell interactions observed in vitro. The mouse model is also a useful system for studying hormonal influences on bacterial-host cell interactions, which is an exciting but understudied area. Finally, the mouse model has accelerated product testing, which is greatly needed for gonorrhea, and can be adapted to develop STI coinfection models.

ACKNOWLEDGMENTS
We thank the numerous collaborators who sent us bacterial strains, vaccine antigens, microbicides, and therapeutic compounds to test in the estradiol-treated mouse model. Their participation has been invaluable in the development of this experimental system for gonorrhea research. This work was supported by NIH/NIAID R01 AI42053 and U19 AI31496.
