Non-alcoholic fatty liver disease: The diagnosis and management

Shehab M Abd El-Kader, Eman M Salah El-Den Ashmawy

Abstract

Non-alcoholic fatty liver disease (NAFLD) is now the most frequent chronic liver disease that occurs across all age groups and is recognized to occur in 14%-30% of the general population, representing a serious and growing clinical problem due to the growing prevalence of obesity and overweight. Histologically, it resembles alcoholic liver injury but occurs in patients who deny significant alcohol consumption. NAFLD encompasses a spectrum of conditions, ranging from benign hepatocellular steatosis to inflammatory nonalcoholic steatohepatitis, fibrosis, and cirrhosis. The majority of hepatocellular lipids are stored as triglycerides, but other lipid metabolites, such as free fatty acids, cholesterol, and phospholipids, may also be present and play a role in disease progression. NAFLD is associated with obesity and insulin resistance and is considered the hepatic manifestation of the metabolic syndrome, a combination of medical conditions including type 2 diabetes mellitus, hypertension, hyperlipidemia, and visceral adiposity. Confirmation of the diagnosis of NAFLD can usually be achieved by imaging studies; however, staging the disease requires a liver biopsy. Current treatment relies on weight loss and exercise, although various insulin-sensitizing agents, antioxidants and medications appear promising. The aim of this review is to highlight the current information regarding epidemiology, diagnosis, and management of NAFLD as well as new information about pathogenesis, diagnosis and management of this disease.

Key words: Non-alcoholic fatty liver disease; Non-alcoholic steatohepatitis; Liver disease

PREVALENCE AND EPIDEMIOLOGY
NAFLD is defined as either excessive fat accumulation in the liver with more than 5% of hepatocytes containing visible intracellular triglycerides or steatosis affecting at least 5% of the liver volume or weight in patients consuming less than 30 g (three units) of alcohol per day for men and less than 20 g (two units) of alcohol per day for women. One unit of alcohol (10 g) is defined as one glass of beer (25 mL), one glass of wine (20 mL) or one glass of whiskey (3 mL). Globally, NAFLD is the most common form of chronic liver disease among adults and children. However, the prevalence of non-alcoholic steatohepatitis (NASH) in the general population is not known. Depending on the cutoff values used to define the upper limit of normal for aminotransferase levels, the estimated prevalence of NAFLD in the general United States population ranges from 5.4% to 24%, but these values may be underestimations because aminotransferase levels have limited sensitivity for steatosis. Histologic estimates of NAFLD prevalence via preoperative or intraoperative liver biopsy, mainly obtained from individuals evaluated as donors for living-donor liver transplantation, are 33% to 88%. In children, NAFLD prevalence has been estimated to be 9.6%; of great concern, 2% to 8% of children with NAFLD progress to cirrhosis.

ETIOLOGY
NAFLD encompasses a group of conditions, ranging from benign hepatocellular steatosis to inflammatory NASH, fibrosis, and cirrhosis. The causes may be divided into two main categories: (1) acquired or congenital metabolic abnormalities; and (2) toxins and drugs. Potential causes of NAFLD are listed in Table 1.

Obesity is often associated with NAFLD as the degree of steatosis was found to be correlated with body mass index (BMI). However, there is a significant correlation between the degree of steatosis, waist-to-hip ratio and the risk of metabolic syndrome. Also, there is a strong correlation between glucose intolerance, type 2 diabetes mellitus (T2DM) and NAFLD. Moreover, Diabetes mellitus may be an independent predictor of advanced liver cirrhosis, HCC and NAFLD.
The pathogenesis of NAFLD is fully understood, however, no single pathogenic mechanism has been identified. Currently, the development of NASH is considered to be through a “two hit” process. The first “hit” includes accumulation of fat in liver cells, which is usually associated with insulin resistance, central obesity along with triglyceride accumulation inside the liver, and fatty acid metabolism dysregulation that leads to steatosis. The second “hit” causes hepatocyte inflammation and necrosis, which lead to cirrhosis and fibrosis in some patients with NAFLD.

ROLE OF OXIDATIVE STRESS
Oxidative stress has a principal role in the pathogenesis of NAFLD as levels of lipid peroxide are increased in both NASH and hepatic steatosis. Oxidative stress plays a key role in the second “hit”, which also involves lipid peroxidation in steatotic hepatocytes. Induction of hepatic CYP2E1 promotes oxidative stress and lipid peroxidation and mitochondrial dysfunction leads to reactive oxygen species formation. Moreover, immune responses to lipid peroxidation products may share in NAFLD progression.

IMMUNE AND INFLAMMATORY PATHWAYS IN NASH
Adaptive and innate immune dysfunction along with inflammatory pathways is involved in the development of NAFLD. Neutrophils, kupffer cells (KCs), natural killer (NK) cells and dendritic cells play an important role in the pathogenesis of NASH. KCs are activated in acute or chronic liver disease, and this activation increases the pro-inflammatory cytokines, e.g., interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α) and IL-1β, which activate T cells and induce hepatocytes apoptosis. Also, activation of neutrophils increases the release of pro-inflammatory cytokines and leads to oxidative damage to hepatic cells. Moreover, NK cells are abundant in liver tissue and have an anti-fibrotic effect in the liver, and reduction of NK cell activity and levels may increase susceptibility to liver cirrhosis among obese subjects. Therefore, NK cells have a role in the development of liver injury and fibrosis and contribute to NASH and NAFLD development.

NATURAL HISTORY
NAFLD is the most common liver disorder worldwide, affecting 20%-40% of population in Western countries and 5%-40% of the general population across the Asia-Pacific region. The prevalence of NAFLD, including NASH, is rising in parallel with the obesity, T2DM, and metabolic syndrome. A certain proportion of NASH patients progress to cirrhosis and HCC. Previous studies showed that 10%-29% of NASH patients may have liver cirrhosis within 10 years, and 4%-27% of these patients may have HCC (Figure 1). Therefore, NAFLD/NASH will gradually become the major etiology of liver disease.
NAFLD with obesity, diabetes, hypertriglyceridemia, and sleep abnormalities include cardiovascular morbidity and mortality. 85% of patients with NAFLD have at least one such linked to the development of NAFLD, and approximately type 2 diabetes, dyslipidaemia and hypertension are elements constituting the metabolic syndrome such as obesity and insulin resistance. More generally, any disease women), hepatitis B and/or C infection, drug abuse, 30 g/d of ethanol for men and 20 g/d of ethanol for the majority of afflicted individuals, so its workup needs to exclude other causes and that it currently remains undiagnosed in the great persistence hepatomegaly. It is important to recognize that only a minority of subjects has NAFLD been diagnosed and that it currently remains undiagnosed in the great majority of afflicted individuals. NAFLD is a diagnosis of exclusion, so its workup needs to exclude other causes such as significant alcohol consumption (defined as >30 g/d of ethanol for men and 20 g/d of ethanol for women), hepatitis B and/or C infection, drug abuse, autoimmune liver disease, haemochromatosis or Wilson’s disease.

The principal risk factors for developing NAFLD are obesity and insulin resistance. More generally, any elements constituting the metabolic syndrome such as type 2 diabetes, dyslipidaemia and hypertension are linked to the development of NAFLD, and approximately 85% of patients with NAFLD have at least one such constituent. The metabolic syndrome itself is present in 30% of patients with NAFLD. The association of NAFLD with obesity, diabetes, hypertriglyceridemia, and hypertension is well known. However, other associations include cardiovascular morbidity and mortality, sleep abnormalities, psychiatric illness, chronic fatigue and pain syndrome, and abnormalities of the coagulation cascade.

**CLINICAL FEATURES OF NAFLD**

Most subjects with NAFLD are clinically silent and asymptomatic, but can manifest with non-specific symptoms such as right upper quadrant discomfort or fatigue. Liver enzymes are usually minimally perturbed with mostly increased levels of alanine aminotransferase (ALT) and gamma-glutamyl transpeptidase. The diagnosis is often made incidentally in these individuals because of either abnormal liver enzyme levels or radiological features of a fatty liver. In others, NAFLD may be diagnosed either as a result of an unusual appearance of the liver during abdominal surgery or because of persistent hepatomegaly. It is important to recognize that only a minority of subjects has NAFLD been diagnosed and that it currently remains undiagnosed in the great majority of afflicted individuals. NAFLD is a diagnosis of exclusion, so its workup needs to exclude other causes such as significant alcohol consumption (defined as >30 g/d of ethanol for men and 20 g/d of ethanol for women), hepatitis B and/or C infection, drug abuse, autoimmune liver disease, haemochromatosis or Wilson’s disease.

The principal risk factors for developing NAFLD are obesity and insulin resistance. More generally, any elements constituting the metabolic syndrome such as type 2 diabetes, dyslipidaemia and hypertension are linked to the development of NAFLD, and approximately 85% of patients with NAFLD have at least one such constituent. The metabolic syndrome itself is present in 30% of patients with NAFLD. The association of NAFLD with obesity, diabetes, hypertriglyceridemia, and hypertension is well known. However, other associations include cardiovascular morbidity and mortality, sleep abnormalities, psychiatric illness, chronic fatigue and pain syndrome, and abnormalities of the coagulation cascade.

**LABORATORY FEATURES OF NAFLD**

Suspicion for NAFLD is triggered by abnormalities of liver chemistry tests that are usually performed for non-liver-related reasons. About 50% of patients with simple steatosis have higher liver biochemical test levels, which occur in 80% of patients with advanced NAFLD. Also, serum aspartate aminotransferase or ALT level, or both is usually increased up to 1.5- to 4-fold and levels rarely exceed 10 times the upper limit of normal. However, the gamma glutamyl transpeptidase and alkaline phosphatase levels may be elevated, but the serum prothrombin time, bilirubin level and serum albumin level are normal, except in patients with NAFLD-associated cirrhosis. Moreover, about one fourth of NAFLD patients may have antinuclear antibodies (ANA) in low titers (less than 1:320). Serum ferritin level may be higher in 20% to 50% of NAFLD patients and can be considered a marker for advanced disease. Hyperglycemia and dyslipidemia may be detected in 30% to 50% of NAFLD subjects. Laboratory and clinical findings do not correlate with NAFLD histologic severity.

**IMAGING FEATURES OF NAFLD**

The radiologic features of fatty liver disease stem from the increased fat content of the liver parenchyma. The spatial pattern may be diffuse and homogeneous or heterogeneous, with focal fat deposition in an otherwise normal liver or areas of focal fat sparing in a diffusely fatty liver. The homogeneous form is the most common; the heterogeneous and focal forms may simulate perfusion abnormalities, diffusely infiltrative disease, nodular lesions, or masses. Therefore, it is not only important to recognize fatty liver on imaging but also to discriminate it from other pathologic processes. The most important modalities used in the assessment of hepatic steatosis are ultrasonography, computed tomography (CT), and magnetic resonance (MR) imaging and MR spectroscopy. However, plain radiography has no significant role in the assessment of NAFLD.

CT has been widely used in evaluation of NAFLD in adults. Use of ionizing radiation precludes its use as a research tool in children, although fatty liver may be observed in children on scans done for clinical purposes. Deposition of fat in the liver is characterized by a reduction in the attenuation of the hepatic parenchyma. On unenhanced CT, normal liver parenchyma has slightly greater attenuation than the spleen or blood. However, with increasing hepatic steatosis, liver attenuation decreases and the liver may become less dense than the intrahepatic vessels, simulating the appearance on a contrast-enhanced scan. Liver attenuation may be affected by a variety of factors other than liver fat, such as iron, copper, glycogen, fibrosis, edema, or amiodarone use. Assessment of liver fat by CT attenuation may be unreliable, and CT methods are...
insensitive to mild steatosis. The reported sensitivity and specificity of unenhanced CT for detection of moderate/severe steatosis (> 30% on histology) range from 73% to 100% and 95% to 100%, respectively.

At enhanced CT, the presence of iodine contrast interferes with attenuation, adding a new confounding factor. Perfusion alterations, timing of acquisitions, and contrast type, dosage, and injection rate all may influence hepatic and splenic attenuation. Nevertheless, criteria have been proposed to detect hepatic steatosis at enhanced CT, including a liver-spleen attenuation difference of at least 20 HU between 80 to 100 s, or at least 18.5 HU between 100 to 120 s, after intravenous contrast injection (Figure 3). Sensitivity and specificity of these attenuation differences range from 54% to 93% and 87% to 93%, respectively. Ultimately, however, the quantitative criteria for diagnosing fatty liver at enhanced CT are protocol specific and have significant overlap of liver-spleen attenuation values between normal and fatty liver, thereby limiting its clinical role.

MR imaging is more sensitive than CT for hepatic steatosis assessment. Recently, MR imaging provides a highly validated and reproducible hepatic triglyceride content measurement. MR imaging is generally considered the most definitive radiologic modality for the qualitative and quantitative assessment of fatty liver disease but is relatively costly (Figure 4). However, proton MR spectroscopy is evolving to detect not only the full spectrum of steatosis but also other features such as the degree of fibrosis.

Transabdominal ultrasonography is the most common imaging technique to diagnose hepatic steatosis due to its widespread availability, noninvasiveness and low cost. At ultrasonography, diffuse fatty liver is characterized by hyperechogenicity of the liver parenchyma relative to the adjacent right kidney or spleen (the so-called bright liver). Focal fat deposition appears as a hyperechoic area in an otherwise normal liver, whereas focal fat sparing is represented by a hypoechoic area within diffusely hyperechoic liver parenchyma. Other frequently described ultrasound features of fatty liver include decreased visualization of vascular margins, attenuation of the ultrasound beam, loss of definition of the diaphragm, and hepatomegaly (Figure 5).

Ultrasonography has several limitations in the detection of both diffuse and focal hepatic steatosis. It is highly operator dependent, nonreproducible, and limited by abdominal gas and patient body habitus. The last inadequacy is highlighted in this patient population because the majority of cases of fatty liver disease occur in overweight or obese individuals. Similar to CT, however, ultrasonography is not a quantitative method.
and may be unable to distinguish simple steatosis from advanced fibrosis or early cirrhosis. Ultrasonography has low sensitivity and specificity for detecting small amounts of fat in the liver\cite{75}.

Transient elastography, a recently developed technique based on ultrasound monitoring of the passage of a low frequency pressure wave through tissues, has been found to be a promising non-invasive technique for the detection of advanced fibrosis caused by chronic viral hepatitis and NASH\cite{80}, although abdominal obesity may compromise its utility in the NASH patient population\cite{81}.

Scintigraphy with xenon-133 (133Xe) as a nuclear medicine imaging technique was used to detect hepatic steatosis in the 1980s and 1990s but is now no longer incorporated in diagnostic algorithms. 133Xe is a highly fat-soluble gas that, after being inhaled or injected, remains in the fatty tissue after blood pool clearing. The 133Xe hepatic retention ratio is increased in patients with fatty liver\cite{82}.

**HISTOLOGICAL FEATURES OF NAFLD**

The main histologic features of NAFLD are similar to those of alcohol-induced liver disease and include steatohepatitis (fatty liver plus parenchymal inflammation with or without accompanying focal necrosis), steatosis (fatty liver) and varying degrees of fibrosis, including cirrhosis. Steatosis is predominantly macrovesicular and usually is distributed diffusely throughout the liver lobule, although prominent microvesicular steatosis and zone 3 (perivenular) steatosis have been reported occasionally (Figure 6). Mild neutrophilic, lymphocytic, or mixed inflammatory infiltrates also may be observed, and glycogenated nuclei are common\cite{69}. NASH, which is an advanced form of NAFLD, is indistinguishable histologically from alcoholic hepatitis (Figure 7)\cite{83}.

Literature reviews indicate that similar factors and markers of inflammation are present in paediatric NAFLD as in adults\cite{84-86}. However, many differences are noted in comparison to adult histology and include: (1) greater severity of steatosis; (2) less or no ballooning or Mallory-Denk bodies; (3) less lobular inflammation; (4) few or no polymorphonuclear leukocytes; and (5) increased portal tract inflammation and fibrosis\cite{87}. Moreover, cirrhosis in children is rare but is reported\cite{88}.

**DIAGNOSIS**

Establishing a definitive diagnosis of NAFLD requires both clinical and histologic data (Figure 8). Most patients with NAFLD are evaluated because of chronically elevated liver biochemical test levels, with or without hepatomegaly. The combination of the patient’s history, clinical examination, radiologic findings and blood test results is essential for accurate diagnosis of NAFLD\cite{89}. Anti-smooth muscle antibodies and ANA are common in patients with NASH and most frequently represent a nonspecific antibody response that is not associated
with the pattern or severity of injury on liver biopsy\(^{[96]}\). However, alcoholic liver disease must be excluded in order to establish NAFLD diagnosis.

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of fatty liver is confirmed by imaging studies and the clinician is challenged with establishing the etiology of hepatic steatosis. Among patients with elevated serum aminotransferase values, the etiology is usually established through a careful evaluation of their history (medication use, risk factors for viral hepatitis, history of alcohol and drug use, and review of comorbidities), a series of screening blood tests for causes of chronic liver disease (viral serologic studies, iron studies, autoimmune markers, ceruloplasmin, and \( \alpha \)-1-antitrypsin), supportive imaging studies (initial evaluation usually by ultrasonography), and, at times, liver biopsy\(^{[91,92]}\).

Alcoholic liver disease includes a spectrum of conditions provoked by alcohol ingestion, including alcoholic hepatitis, fatty liver disease and cirrhosis. It has been estimated that almost all patients with heavy alcohol consumption develop fatty liver, although only 10% to 35% develop alcoholic hepatitis and 8% to 20% progress to alcoholic cirrhosis\(^{[93]}\). In individuals who admit to moderate alcohol intake, the differentiation between NAFLD and alcoholic fatty liver disease is difficult because laboratory, imaging, and histologic findings are similar. Unfortunately, strong data are lacking to determine accurate thresholds for alcohol consumption required to cause fatty liver. Historically, daily alcohol intake of 30 g in men and 20 g in women has been used to distinguish NAFLD from alcoholic fatty liver disease, although the validity of these thresholds is unknown\(^{[94]}\). If liver biopsy specimens are obtained, individuals with alcoholic liver disease tend to have more Mallory’s hyaline and acidophil bodies and less glycogenated nuclei than those with NAFLD, although these are not reliable findings\(^{[94]}\).

Because the radiologic findings of hepatic steatosis are common to its diverse causes, the differential diagnosis is largely discriminated on clinical and laboratory grounds\(^{[95]}\). Special attention needs to be given to the possible imaging overlap between simple steatosis and advanced fibrosis or early cirrhosis; these disparate conditions are often, but not always, easily distinguished clinically. A major challenge in the differential diagnosis of hepatic steatosis occurs when the radiologic findings of focal fat deposition or focal fat sparing simulate hepatic nodular lesions such as abscess, benign neoplasm, or primary or metastatic malignancy. The diagnosis of focal fat deposition or sparing is supported by its occurrence in typical locations, a wedge shape, the lack of mass effect, and the absence of vascular displacement or distortion inside the lesion. When there is still doubt, MR imaging may be performed\(^{[89]}\).

Certain drugs may produce de novo steatohepatitis (e.g., amiodarone, perhexiline maleate, diethylaminoethoxyhexestrol) and others may exacerbate NASH (tamoxifen, corticosteroids, diethyl stilbestrol, estrogen)\(^{[96]}\). Oxaliplatin and irinotecan administered as preparative chemotherapy before surgical resection of hepatic metastases have been associated with steatohepatitis, with irinotecan-associated steatohepatitis associated with poorer outcomes after hepatic resection\(^{[97,98]}\). Other conditions capable of eliciting fatty liver include intestinal bypass surgery for weight loss (classically seen with jejunoileal bypass surgery), human immunodeficiency virus (HIV) infection with lipodystrophy, and parenteral nutrition\(^{[99]}\). If any of the above secondary causes of fatty liver are excluded (alcohol, viral hepatitis, drug-induced, jejuneeileal bypass surgery, HIV infection, and parenteral nutrition support), a diagnosis of NAFLD can be made\(^{[100]}\).

**GRADING AND STAGING**

The standardized schema of NAFLD staging and grading was published by Brunt and associates in 1999, who assigned the overall grade of mild, marked, or severe (grades 1, 2, and 3, respectively), based on the degree of ballooning degeneration, steatosis and lobular and portal inflammation as listed in Table 2\(^{[99]}\). The Pathology Committee of the National Institute of Diabetes and Digestive and Kidney Diseases sponsored NASH Clinical Research Network maintained features of the Brunt schema for NAFLD grading as found in Table 3\(^{[10]}\).

**TREATMENT**

To date, there are no established treatment guidelines
and no single approved therapy for NAFLD treatment. Historically, the principal treatment for NAFLD consisted of removal of offending drugs and toxins, weight loss, and control of associated metabolic disorders as hyperlipidemia and diabetes. The focus of NAFLD management is to ameliorate the NASH risk factors (i.e., insulin resistance and obesity), with the objective of preventing disease progression or regression of already established fatty liver or NASH. Lifestyle changes and dietary modification are the main methods for weight management.

Weight management
The ultimate weight management goal is to achieve the ideal body weight. However, significant insulin resistance improvement could be attained by modest weight loss[100].

The National Heart, Lung, and Blood Institute guidelines for weight management in obese subjects are the best evidence-based treatment guidelines, which generally recommended that the diet should be planned to achieve a daily caloric deficit of 500 to 1000 calories along with an increase in everyday activities[101]. Furthermore, for subjects with a BMI higher than 30 kg/m² or with a BMI higher than 27 along with other comorbid conditions (e.g., sleep apnea), pharmacologic weight management with orlistat or sibutramine may be considered as these agents could produce a beneficial effect on NAFLD[99]. However, both vertical banded gastroplasty and proximal gastric bypass have been shown to be safe in NASH subjects[102]. Moreover, the severity of hepatic steatosis, fibrosis and cell injury regresses once the weight stabilizes following these operations[103].

Pharmacologic treatment of NASH
Several drug therapies have been tried in both research and clinical settings, yet no agent has been approved by the Food and Drug Administration for the treatment of NAFLD[103].

Vitamin E
Vitamin E, an inexpensive potent antioxidant, has been examined as a treatment agent for NAFLD in many adult and pediatric studies, with varying results. In all studies, vitamin E was well tolerated, and most studies showed modest improvements in ultrasonographic appearance of the liver, serum aminotransferase levels and histologic findings[97,104,105]. In one published series of 11 pediatric patients with NASH who received vitamin E (d-α-tocopherol), 400 to 1200 IU, ALT improved[105-107].

Lipid-lowering agents
Few small trials assessed the usefulness of lipid-lowering and cytoprotective drugs for NAFLD treatment, with varying results. In one controlled trial, gemfibrozil improved liver chemistry in 74% of NAFLD patients in the treatment group, compared with 30% of untreated control subjects with no available histologic data. So, in general, lipid-lowering agents are not used for NASH treatment[108].

Insulin sensitizers
The association between hyperinsulinemic insulin resistance and NAFLD provides a logical target for treatment. Two classes of drugs have been shown to correct insulin resistance: biguanides (e.g., metformin) and thiazolidinediones. Metformin, a biguanide that reduces hyperinsulinemia and improves hepatic insulin sensitivity, reduces hepatomegaly and hepatic steatosis in ob/ob mice[109], but results in human studies have been less impressive[110,111] as in human studies, although ALT improved and liver size decreased, metformin was not consistently found to improve liver histology[110,112].

Ursodeoxycholate
Ursodeoxycholate (UDCA) is a hydrophilic bile acid that is associated with hepatoprotective properties. In one study, UDCA produced improvement in liver enzymes and a decrease in hepatic steatosis. The long-term benefits of UDCA and the optimal dose of UDCA remain to be established[113].

Taurine
Taurine is believed to function as a lipotropic factor and to improve the mobilization of hepatic fat. In another single uncontrolled series, 10 children treated with taurine supplements orally had radiologic resolution of their fatty liver[114].

Betaine
Betaine is a hepatoprotective factor, and liver histology and aminotransferase activity were improved in ten NAFLD subjects who received betaine for one year[115,116]. In a recent randomized placebo-control study, 55 NASH patients received betaine (20 g daily). Patients randomized to betaine had a decrease in steatosis grade without a significant change in intragroup or intergroup differences in NAS or fibrosis stage. Moreover, there was no significant change in adiponectin, insulin, glucose, proinflammatory cytokines, or oxidant stress in NASH

Table 3  Non-alcoholic fatty liver disease activity score[9]

| Score | Steatosis |
|-------|----------|
| 0     | < 5%     |
| 1     | 5%-33%   |
| 2     | > 33%-66% |
| 3     | > 66%    |
| Lobular inflammation (counted in 20 × fields) |
| 1     | < 2 foci |
| 2     | 2-4 foci |
| 3     | > 4 foci |
| Ballooning |
| 1     | Few      |
| 2     | Many     |
patients receiving betaine therapy\textsuperscript{[116]}.  

**Pentoxifylline**  
Pentoxifylline antagonizes TNF-α and is orally available for long-term use. In two small pilot studies, ALT improved after several months of treatment at a dose of 400 mg three times a day. In addition, although the drug was well tolerated in one study, 9 of 20 subjects in the other study dropped out because of side effects, especially nausea\textsuperscript{[117,118]}.  

**Losartan**  
Angiotensin II has been implicated in hepatic stellate cell activation and matrix production\textsuperscript{[119]}. In a small pilot study of an angiotensin receptor blocker, losartan, an improvement in ALT was noted\textsuperscript{[120]}.  

**Surgical treatment**  
Bariatric surgery is the primary surgical intervention for NAFLD in patients with an BMI more than 40 kg/m\textsuperscript{2} or of 35 kg/m\textsuperscript{2} with comorbidities\textsuperscript{[121]}. Current bariatric surgical techniques include vertical banding gastroplasty, Roux-en-Y gastric bypass, biliopancreatic bypass, and biliopancreatic diversion with duodenal switch. Based on a recent meta-analysis, bariatric surgery is associated with significant histologic improvements in steatosis, steatohepatitis, and fibrosis, with more than 50% of patients experiencing complete resolution of their fatty liver disease after surgery. Although these results are compelling, these observational studies showed no relationship between histologic improvement and the amount of weight loss\textsuperscript{[122]}.  

As with other causes of cirrhosis, liver transplantation is a viable option for patients with end-stage liver disease due to fatty liver disease\textsuperscript{[123]}. The outcome of liver transplantation in these patients is good, although NAFLD can recur after liver transplantation\textsuperscript{[124-125]}.
