*Cite as*

Clematis is a superior perennial ornamental vine known for varied colors and shapes of its flowers. *Clematis crassifolia* is sensitive to high temperature, whereas *Clematis cadmia* has a certain temperature adaptability. Here we analyzed the potential regulatory mechanisms of *C. crassifolia* and *C. cadmia* in response to heat stress by studying the photosynthesis, antioxidant parameters, amino acids, and gene expression patterns under three temperature treatments. Heat stress caused the fading of leaves; decreased net photosynthetic rate, stomatal conductance, superoxide dismutase, and catalase activity; increased 13 kinds of amino acids content; and up-regulated the expression of seven genes, including C194329_G3, C194434_G1, and C188817_g1, etc., in *C. crassifolia* plants. Under the treatments of heat stress, the leaf tips of *C. cadmia* were wilted, and the net photosynthetic rate and soluble protein content decreased, with the increase of 12 amino acids content and the expression of c194329_g3, c194434_g1, and c195983_g1. Our results showed that *C. crassifolia* and *C. cadmia* had different physiological and molecular response mechanisms to heat stress during the ecological adaptation.

**Keywords:** *Clematis crassifolia*, *Clematis cadmia*, heat stress, physiological analysis, gene expression

**INTRODUCTION**

*Clematis* is a large genus that belongs to Ranunculaceae and has great ornamental value. There are various species of *Clematis*, which have rich variations in colors and shapes of flower. *Clematis* can be widely used in flower stands, corridors, lamp pillars, fences, arches, and other configurations to form an independent landscape, and it occupies a very important position in landscaping (Lehtonen et al., 2016). *Clematis* also has a certain medicinal value, which can be used as anti-inflammatory, antirheumatism, and analgesic agents (Hao et al., 2013; Li et al., 2017). There are approximately 355 species of *Clematis* in the world and 147 species in China (Pringle, 1971; Liu et al., 2018). In terms of adaptability to the environment, *Clematis* prefers a cool climate and is often associated with shrubs in the wild. At present, most cultivars of *Clematis* on the market are susceptible to high temperature in summer (Gao et al., 2017; Jiang et al., 2020). After the heat stress, the leaves will fade, wilt, and fall off, stem will wither, and there will be other heat damage symptoms, which severely affects the ornamental characteristics of *Clematis*. 
With the global warming caused by the greenhouse effect, the heat stress has become one of the most important abiotic stresses that restrict plant growth (Berry and Bjorkman, 1980). In recent years, the frequent occurrence of extreme high temperature posed a severe challenge to the ability of plants to withstand high temperatures (Hasanuzzaman et al., 2013; Borrell et al., 2020). Therefore, the regulatory mechanism of plants in response to heat stress and the cultivation of heat-resistant varieties have become a focus of attention. Plants have produced a series of adaptation mechanisms to resist heat stress in the process of evolution (Wahid et al., 2007). One is heat resistance, which strengthens plants by changing leaf orientation, increasing leaf trichomes, and increasing xylem cells (Tozzi et al., 2013; Bickford, 2016). The other is heat tolerance mechanism, which is involved in a series of signal pathways, including ion transporters, osmoprotectants, free radical scavengers, signal cascades, and transcription factor regulation (Rodriguez et al., 2008; Ohama et al., 2017).

Previous studies have shown that heat stress changes the components and structure of plant cell membranes, reduces cell membrane integrity, increases cell membrane permeability, and causes the ion leakage (Wise et al., 2004; Bita and Gerats, 2013; Lohani et al., 2020). Heat stress can cause plants to accumulate excess reactive oxygen species (ROS), break the balance of ROS in cells, inhibit the photosynthetic electron transport chain, and cause irreversible damage to photoresponse system II while intensifying membrane lipid peroxidation (Ahmad et al., 2010; Gururani et al., 2015; Choudhury et al., 2017). Plants have evolved both enzymatic and nonenzymatic systems to remove ROS to maintain the growth of plants. The currently reported enzymatic antioxidant systems include superoxide dismutase (SOD), catalase (CAT), and ascorbic peroxidase (APX), etc. Nonenzymatic antioxidants are antioxidants in plants such as proline, ascorbic acid, mannitol, and glutathione, etc (Hameed et al., 2012; Tripathy and Oelmüller, 2012). In Lilium longiflorum, the antioxidant enzyme activities including SOD, peroxidase (POD), CAT, APX, and glutathione reductase (GR) were stimulated after 10 h of high-temperature treatment at 37°C and 42°C, and the concentrations of ascorbic acid (AsA) and glutathione (GSH) were maintained at a high level, resulting in the decrease of ROS content, so as to mitigate the damage caused by heat stress (Yin et al., 2008). The accumulation of osmotic regulation substances is also an important physiological mechanism for plants to respond to heat stress (Kaplan et al., 2004).

The up-regulated expression of genes has been reported to help plants adapt to heat stress (Atkinson and Urwin, 2012). Heat shock proteins (HSPs) are a type of stress protein that is induced in organisms under the heat stress (Jacob et al., 2017). They are involved in protein synthesis, folding, cell localization, protein transmembrane transport, and target protein degradation to maintain the stability of the plant homeostasis (Qu et al., 2013; Xu et al., 2016). Heat shock transcription factors (HSFs) are the key regulator of plant response to heat stress and play a critical role in the regulation of plant heat stress response (Guo et al., 2016). HsfA1 was an important transcription factor for Arabidopsis thaliana to obtain heat resistance (Ohama et al., 2016). The transcription factor FaHsfA2c of Festuca arundinacea was upregulated in leaves and roots under heat stress, which could enhance the heat resistance of F. arundinacea (Wang et al., 2017). In tomato (Solanum lycopersicum), Mishra founded that plants with silenced of HsfA1a were more sensitive to heat stress than wild type in each developmental stage (Mishra et al., 2002). HsfB1 was a transcriptional inhibitor, and it could also be used as coactivator of HsfA1a to inhibit the expression of HsfA1b and HsfA2 (Röth et al., 2017; Zhou et al., 2018).

As an excellent ornamental vine, the market demand for Clematis is constantly rising in the world. However, the continuous loss of wild resources and the limited heat tolerance of horticultural varieties put forward a severe test to the cultivation of Clematis. How to effectively improve the heat resistance and reduce the damage of heat stress is the emphasis work of cultivation and breeding of Clematis. Clematis crassifolia is a kind of evergreen species, which blooms in winter and is mostly distributed in dense forests or sparse forests with an altitude of 100~300 m in China. Clematis cadmia is a potential material for resistance breeding because of its strong resistance and abundant flowers. In preliminary study, we found that C. cadmia has a certain temperature adaptability, whereas C. crassifolia was more sensitive to temperature in summer, so it is necessary to analyze the physiological and biochemical differences between C. crassifolia and C. cadmia. In this study, in order to understand the effects of heat stress on Clematis, we explored the response of photosynthesis, antioxidant enzyme activity system, amino acid levels, and gene expression in C. crassifolia and C. cadmia, which is expected to provide a theoretical foundation for the cultivation and breeding of C. crassifolia and C. cadmia.

**MATERIALS AND METHODS**

**Plant Materials and Growth Conditions**

Plants of C. crassifolia and C. cadmia were grown under different heat stress and conducted in the Zhejiang Institute of Subtropical Crops (120°37′53″E, 28°08′0″N), China. Two-year-old healthy and homogenous plants were grown in a grown chamber under a 16/8-h long-day cycle at 25°C/20°C, 65% humidity for 2 weeks. After 2 weeks of pretreatment, in order to carry out the heat stress, the pretreated plants of C. crassifolia and C. cadmia were transferred to the grown chamber for cultivation at 25°C/20°C, 35°C/30°C, and 45°C/40°C temperature, respectively. Heat stress treatments lasts for 4 days; during the treatment period, water was poured every 2 days, 500 mL each time, to ensure sufficient soil moisture. Take the mature leaves of two to five positions after 4 days of treatments, respectively. Fresh leaves were tested for physiological indicators, and other samples were frozen in liquid nitrogen and stored at −80°C for the analysis of amino acid and gene expression. Experimental treatments were repeated three times.

**Leaf Gas Exchange Parameters**

Healthy and fully developed leaves from each treatment were randomly chosen for photosynthetic parameter measurements, using LI-6400 XT portable photosynthesis system (Li-Cor Inc., Lincoln, NE, United States), and equipped with a 6400-18 RGB
LED light source. The measurements were carried out from 9:00 to 11:00 AM, the photosynthetic photon flux density was 1200 \( \mu \text{mol m}^{-2} \text{s}^{-1} \), the \( \text{CO}_2 \) concentration was 400 ppm, and the relative humidity was 65%.

**Photosynthetic Pigments**

The finely cut and well-mixed leaf samples (100 mg) were transferred to a 10 mL tube. Then, 8 mL of 80% acetone was added to the test tube and mixed. Chlorophyll was extracted at 4°C in the dark. The absorbance of supernatant was measured at 663, 645, and 470 nm with a spectrophotometer (Shimadzu UV-2550, Kyoto, Japan). The total chlorophyll content was calculated and was expressed as mg g⁻¹ FW. The total chlorophyll content was measured according to the described method by Lichtenthaler and Buschmann (2001).

**Measurement of MDA Content, Hydrogen Peroxide Content, and Soluble Protein Content**

The malondialdehyde (MDA) content was determined as previously described (Ouyang et al., 2010).

The \( \text{H}_2\text{O}_2 \) content and soluble protein content were measured according to the method as previously described (Luo et al., 2012).

**Determination of SOD, CAT, and POD Activity**

For antioxidant enzyme activity analysis, fresh leaves (0.1 g) were ground in liquid nitrogen and then suspended in 8.0 mL solution containing 50 mM phosphate buffer (pH 7.4). The homogenate was centrifuged 10,000 rpm for 15 min at 4°C, and the supernatant was collected to obtain crude enzymes.

The SOD activity was analyzed by measuring the inhibiting rate of the enzyme to \( \text{O}_2^- \) produced. One-unit SOD activity (U) was defined as the amount of enzyme that resulted in 50% inhibition of reduction of nitrite in 1 mL reaction solution. The SOD activity was determined at 550 nm after 40 min of reaction at 37°C and expressed as U g⁻¹ FW (Ma et al., 2017).

The CAT activity was determined by the hydrolysis reaction of hydrogen peroxide (\( \text{H}_2\text{O}_2 \)) with CAT; the reaction could be terminated rapidly by molybdenum acid (MA) to produce yellow MA-H\(_2\)O\(_2\) complex (Li et al., 2013). The CAT activity was calculated in absorbance at 405 nm. One unit was defined as the amount of enzyme that resulted in the decompose of 1 \( \mu \text{mol} \) \( \text{H}_2\text{O}_2 \) per second in 1.0 g fresh tissue.

The POD activity was measured based on the change of absorbance at 470 nm by catalyzing \( \text{H}_2\text{O}_2 \) (Zheng et al., 2018). One unit was defined as the amount of enzyme that resulted in the change of 0.01 at 470 nm per minute by 1.0 g fresh tissues in the reaction system.

**Amino Acid Contents Analysis**

Samples (10 mg) were weighed, mixed with 1 mL methanol, and subsequently homogenized in an ultrasonic instrument for 3 min, tubes were static for 5 min at room temperature, and 10,000 rpm centrifuged for 15 min at 4°C. The supernatant was diluted 10 times. One hundred microliters of dilution was transferred to heat-resistant tubes, and 100 \( \mu \text{L} \) of internal standard solution (100 ppb) was added; the mixture was filtered through a 0.45-\( \mu \text{m} \) membrane and then injected into the Ultra Performance Liquid Chromatography (UPLC) for analysis. The 24 kinds of standards were weighed accurately. Stock solutions were prepared using methanol or water, and a series of mixed working standard solutions were properly prepared and diluted with water. The standard solutions were stocked under 0°C.

UPLC separation was performed on an Acquity UPLC system (Waters, United Kingdom) equipped with an ACQUITY UPLC® BEH HILIC (1.7 \( \mu \text{m}, 2.1 \times 100 \text{ mm}, \text{Waters}) column. The temperature of the column was set at 40°C. The sample injection volume was 5 \( \mu \text{L} \). Eluents consisted in water/methanol (90:10) with 0.1% (vol/vol) formic acid (eluent A) and water/methanol (50:50) with 0.1% (vol/vol) formic acid (eluent B). The gradient elution started with 10% B for 0 min, ramped to 30% of B within next 6.5 min, ramped to 100% of B in 7 min, kept at 100% of B until 8 min and dropped to 10% B in 8.5 min at a flow rate of 0.3 mL/min, and finally kept at 10% of B until 12.5 min at a flow rate of 0.4 mL/min.

The MS analysis was performed using a AB 4000 mass spectrometer (AB, United States) equipped with an ESI source in the positive-ion mode working in the multiple reaction monitoring mode. An ion source voltage of 5.5 kV and a source temperature of 500°C were used. Collision gas and the curtain gas were set at 6 and 30 psi, respectively, whereas both of the atomization gas and auxiliary gas were 50 psi.

**Gene Expression**

Isolation of total RNA from the leaf tissues and real-time quantification of transcriptional expression of the genes were the same as that reported previously (Ma et al., 2019). All of the primers used for quantitative reverse transcriptase–polymerase chain reaction (PCR) are listed in Supplementary Tables 1, 2. All of the PCR products were confirmed by sequencing.

**Statistical Analysis**

Data were analyzed by two-way analysis of variance (ANOVA) using the SPSS 10 program (SPSS Inc., Chicago, IL, United States). Different letters on the histograms between different treatments indicate their statistical difference at \( P \leq 0.05 \).

**RESULTS**

**High-Temperature Stress Caused Leaf Discoloration and Crimping of C. crassifolia and C. cadmia**

Under different temperature treatments, the leaves damage degree of C. crassifolia and C. cadmia showed significant differences. In comparison with the normal-temperature treatment (25°C), C. crassifolia mainly showed water loss, leaf carnification degree reduced, and leaf turned yellow (Figure 1B). C. cadmia exhibited partial curling with the yellow leaf tips.
Heat Stress Response of Clematis

FIGURE 1 | Effect of heat stress on the morphology of the leaves of C. crassifolia and C. cadmia. (A) Treatment conditions. (B) The phenotype of C. crassifolia leaves. (C) The phenotype of C. cadmia leaves. Bar means 1 cm.

(Figure 1C). In addition, after 45°C heat stress treatment, the MDA content of C. crassifolia was increased 443.97% compared with normal-temperature treatment (25°C). No significant differences were observed in C. cadmia between two heat stress treatments (Supplementary Figure 1).

Heat Stress Inhibited the Photosynthesis of C. crassifolia and C. cadmia

The heat stress can aggravate the degradation of chlorophyll and inhibit its synthesis, so the change of chlorophyll content can reflect the damage degree of high temperature to plants (Zhou and Leul, 1999). According to the heat stress treatments, the Chla, Chlb, and carotenoid content of C. crassifolia were decreased, instead of the increased Chla/b ratio. Even at the same heat stress condition, C. cadmia plants have high photosynthetic pigments than C. crassifolia; the Chla and Chlb content under the moderate (35°C) temperature increased by 31.59% and 24.10%, respectively, compared with those under the normal temperature (25°C) in C. cadmia, and decreased by 21.59% and 14.79% under high (45°C) temperature compared with the normal temperature (25°C), respectively (Figure 2).

The photosynthetic parameters of C. crassifolia and C. cadmia were also strikingly affected by heat stress treatments. The net photosynthetic rate ($\text{P}_n$) of C. crassifolia and C. cadmia showed significant decrease in high-temperature treatment (45°C), which were only 1.29% and 3.25% of normal-temperature treatment (25°C), respectively (Figure 3A). With the increase of temperature, the variation trends of stomatal conductance (Gs), intercellular CO$_2$ concentration (Ci), and transpiration rate (TR) of C. crassifolia and C. cadmia were similar. C. crassifolia plants grown under 45°C condition have extremely low Gs and TR values, decreased 71.58% and 65.80%, respectively, compared with the plants under normal temperature (25°C). However, the Gs, Ci, and TR of C. cadmia has no significant difference between 25°C and 45°C treatments (Figures 3B–D).

The Antioxidant System of C. crassifolia Was More Influential Than C. cadmia Under Heat Stress

The activities of POD and SOD in C. cadmia leaves were significantly affected by heat stress treatments. The POD activity was 1.95 times that in the normal-temperature treatment (25°C). The SOD activity was decreased significantly with different heat stress, by 27.33% and 32.79%, respectively. In C. crassifolia, there was no significant difference of POD activity among three temperature degrees, but SOD activity decreased gradually with the increase of temperature (Figure 4).

The CAT activity of C. crassifolia was significantly inhibited by heat stress. Under the condition of 45°C heat stress, the activity of CAT decreased by 91.76%, whereas there was no significant change in C. cadmia plants (Figure 5A), while the H$_2$O$_2$ content in C. crassifolia was increased obviously by gradient with the increase of temperature, increased by 60.64% and 215.54%, respectively, under moderate (35°C) and high (45°C) temperature compared with the normal temperature (25°C). The C. cadmia plants exposed to high-temperature treatment (45°C) showed 150.60% increase of the H$_2$O$_2$ content than those under normal (25°C) treatment (Figure 5B).

The Content of Soluble Protein and Amino Acid in C. crassifolia and C. cadmia Showed Difference Patterns Under Heat Stress

After different heat treatments, the soluble protein content of C. cadmia decreased 45.67% under high-temperature treatment (45°C) compared with normal-temperature treatment.
(25°C); however, there was no significant change of soluble protein content in *C. crassifolia* plants under heat-stressed conditions (Figure 6).

The amino acid content was assessed in *C. crassifolia* and *C. cadmia* plants under different heat stress treatments (Table 1). Isoleucine, glutamine, histidine, and tryptophan were significantly increased in both *C. crassifolia* and *C. cadmia* plants under moderate-temperature (35°C) and high-temperature (45°C) treatments compared with normal-temperature treatment (25°C). Ornithine hydrochloride was only detected in *C. crassifolia* plants, and glycine was only detected in *C. cadmia* plants under 45°C heat treatment. Proline, valine, threonine, lysine, phenylalanine, and tyrosine were up-regulated at 45°C condition in *C. crassifolia* and at 35°C treatment in *C. cadmia* (Table 1).

**Gene Expression Pattern in *C. crassifolia* and *C. cadmia* Under Heat Stress**

To explain the response of *C. crassifolia* and *C. cadmia* plants to heat stress, we examined the expression of 12 genes under 45°C culture condition, including HSP, HSF, photosystem, and POD genes, which were described in transcriptome profiling (Figure 7). The transcript levels were significantly different in *C. crassifolia* and *C. cadmia*. The expression levels of HSP and HSF genes including c194329_g3 and c194434_g1 in *C. cadmia* were remarkably higher (>2.0-fold) after heat stress, and those two genes have significant up-regulation in *C. crassifolia* except endure the heat stress for 12 h (Figures 7A,B). Four genes associated with heat stress, including c188817_g1, c200811_g3, c187075_g1, and c194962_g2, which were involved in biosynthesis of photosystem and chlorophyll, have high transcript levels after heat stress in *C. crassifolia* plants, and only c188817_g1 and c208712_g3 showed a small amount of increase after 6 h of heat stress treatment in *C. cadmia*. For antioxidant enzyme genes, the transcript level of c199977_g2 has substantially increased in *C. crassifolia* after heat stress, and the expression of c202620_g2, c195983_g1 and c198009_g1 varied slightly in *C. cadmia* (Figures 7C,D).

**DISCUSSION**

With the aggravation of greenhouse effect and the rise of global temperature, heat stress is the main environmental stress that restricts plant growth and development. Plants respond
Hu et al. Heat Stress Response of Clematis

**FIGURE 3** | Photosynthetic parameters of *C. crassifolia* and *C. cadmia* grown under three different temperatures including normal temperature (25°C), moderate temperature (35°C), and high temperature (45°C). (A) Net photosynthetic rate ($P_n$). (B) Stomatal conductance ($G_s$). (C) Intercellular CO$_2$ concentration ($C_i$). (D) Transpiration rate ($T_r$). Error bars indicate SE ($n = 5$ plants). To heat stress through changes in physiological, biochemical, and transcriptional regulatory systems (Baniwal et al., 2004; Rizhsky et al., 2004; Wu et al., 2018). This study presents the leaves phenotype, physiological mechanism, and gene expression pattern of *C. crassifolia* and *C. cadmia* in response to different heat stress. The damage to plant organs, tissues, and cells caused by heat stress was multifold. Plants exposed to heat stress damage showed discoloration or peeling of leaves, damage of flowers and fruits, poor seed germination rate, and inhibition of plant growth (Rodríguez et al., 2005). With the increase of temperature, *C. crassifolia* and *C. cadmia* manifested different symptoms of heat damage. The fading and wilting leaves were observed in *C. crassifolia*, whereas *C. cadmia* leaves showed rolling and drying in leaf tip and leaf margins (**Figure 1**).

Photosensitive pigment regulation is an important regulation mechanism of photosynthesis protection in plants under heat stress. Increasing the chlorophyll content with a certain range can improve the absorption and transformation of light energy by plants (Shi et al., 2006). In this study, the content of Chla and Chlb decreased under the 45°C heat stress and caused a 35.49% increase in Chla/b and a 40.84% decrease in *C. crassifolia* (**Figures 2A–C**), indicating that Chlb was more sensitive to heat stress than Chla in *C. crassifolia*. Heat stress affects the early stage of photosynthesis and mainly changes the membrane properties of chloroplasts and the uncoupling of energy transfer mechanism, but protein denaturation under continuous heat stress can cause irreversible damage (Fan et al., 2018). The reasons for the decrease of $P_n$ in plant leaves are mainly divided into stomata limiting factors and non-stomata-limiting factors. The previous studies have observed that the heat stress can cause plant stomatal closure and reduce the photosynthetic rate (Crafts-Brandner and Salvucci, 2002; Pnueli et al., 2003).

In this study, the $P_n$, $G_s$, and $T_r$ of *C. crassifolia* were significantly reduced under heat stress of 45°C, indicating that heat stress caused the decline in photosynthesis of *C. crassifolia* by
both stomata-limiting factors and non–stomata-limiting factors. The total chlorophyll content of \textit{C. cadmia} decreased significantly at 45°C heat stress, and there were no significant differences in Gs and Tr, whereas the increased of Gs and Tr were observed in \textit{C. cadmia} plants under 35°C, resulting in a 54.02% increase in Pn. These results indicated that \textit{C. cadmia} can adapt to the environment by increasing the chlorophyll content and Gs under moderate temperature conditions, and the decrease of photosynthetic activity under heat stress was the main reason for the reduction of photosynthesis.

The injury of plants under adversity is closely related to membrane lipid peroxidation induced by the accumulation of ROS (Asada, 2006). MDA is one of the most important products of membrane lipid peroxidation. Therefore, MDA level can be measured as an indirect measure of injury to membrane lipid and stress resistance of plants. In this study, we observed that 45°C heat stress led to a significant increase in MDA content and H$_2$O$_2$ content of \textit{C. crassifolia}; however, there were no significant changes in \textit{C. cadmia} under different temperature treatments (Supplementary Figure 1 and Figure 5B). The results suggested that the high temperature could result in the accumulation of excessive H$_2$O$_2$ in \textit{C. crassifolia}, which would cause the destruction of cell membrane. But \textit{C. cadmia} could maintain a relatively stable cell homeostasis under heat stress.

Plant in long-term evolution formed in the process of enzymatic reaction system in order to eliminate the oxidative stress caused by heat stress and enhance the protection ability of plants, including POD, CAT, and SOD, etc., which play a key role in the regulation of ROS homeostasis in the cell (Larkindale and Vierling, 2008; Vidya et al., 2018). The stress tolerance of tomatoes at heat is closely associated with its antioxidant mechanism (Zhou et al., 2019). In our study, it was shown that \textit{C. crassifolia} and \textit{C. cadmia} could respond to heat stress by
Table 1: Amino acid contents (data shown are the mean) of C. crassifolia and C. cadmia grown under different temperature treatments.

| Amino acid          | Absolute content (µg g⁻¹) | C. crassifolia 25°C | C. crassifolia 35°C | C. crassifolia 45°C | C. cadmia 25°C | C. cadmia 35°C | C. cadmia 45°C |

Different letters indicate significant differences based on two-way ANOVA followed by Tukey multiple comparisons (P ≤ 0.05).
regulating the antioxidant mechanism, but sustained heat stress would reduce the enzyme activity.

Amino acids are a class of important physiological active substances. Substances such as amino acids or polyamines synthesized with amino acids as precursors can accumulate under heat stress, stabilize proteins, and maintain cell osmotic pressure (Bowlus and Somero, 1979). Glycine, as an important amino acid, is a synthetic substrate of glycine betaine (GB), which can protect photosystem II, stabilize membranes, and reduce oxidative damage (Sita et al., 2018; Alhaithloul et al., 2020). γ-Aminobutyric acid (GABA) is a nonprotein amino acid widely present in plants. Under heat stress, GABA can improve the activity of antioxidant enzymes such as POD and CAT to reduce peroxidation damage (Nayyar et al., 2014). Exogenous application of GABA could enhance accumulation of osmolytes such as proline and trehalose due to increase in the activities of their biosynthetic enzymes and improved the leaf turgor, carbon fixation, and assimilation processes to protect the reproductive function from heat stress in mungbean (Priya et al., 2019). In this study, amino acids such as Pro, Val, Thr, Ile, Leu, Glu, Lys, His, and Tyr were increased to relieve osmotic pressure of leaf cell in *C. crassifolia*. *C. cadmia* sufficiently increased the content of amino acids such as Gly, GABA, Glu, and Tyr; maintained the activity of antioxidant enzymes; and reduced the content of MDA, thereby enhancing the stability of cell membrane structure and alleviating the damage caused by heat stress.

Plant response to heat stress involves a complex gene regulatory network, and the damage caused by stress can be alleviated by regulating the expression of related genes (Krasensky and Jonak, 2012). In the previous study, a total of 81 SRAP and 133 EST-SSR polymorphic loci were detected in *Clematis* (Li et al., 2018). HSPs, especially small HSPs, antioxidant enzymes (e.g., APX), and galactosyl alcohol synthesis enzymes play key roles in the heat resistance of grapes (Liu et al., 2012). The HSF HsfA1 plays an important role in transcriptional regulatory networks in promoting the expression of heat stress–related genes, to regulate intracellular protein activity, rehabilitate denatured proteins, degrade misfolded proteins, and alleviate the damage caused by heat stress (Yoshida et al., 2011). We screened out the expression patterns of 12 genes associated with heat stress (Figure 7). The expressions of c194329_g3, c204515_g1, c194434_g1, and c195983_g1 were up-regulated in *C. cadmia* within a short period of heat stress, whereas the response time of *C. crassifolia* was longer. c194329_g3 and c194434_g1 were up-regulated 12 h later. The results showed that *C. cadmia* could rapidly respond to heat shock stress and promote the synthesis of related enzymes and metabolites by enhancing the expression of small HSP, HSFs, and APX genes, thus alleviating the damage caused by heat stress. PsaH is a membrane peripheral protein located at the surface of PSI, and PSBY protein is located in the thylakoid membrane, both of which play an important role in photosynthetic system composition and electron transport.

![Figure 7](image_url) | Effect of heat stress on the gene expression in *C. crassifolia* and *C. cadmia* leaves. Time course of heat in *C. crassifolia* and *C. cadmia* shifted to 45°C. (A,C) *C. crassifolia*. (B,D) *C. cadmia*. Soluble protein content. Bars indicate SE (*n* = 3).
(Obokata et al., 1993; Ozawa et al., 2018). C. crassifolia leaves photosynthetic system response was more sensitive to heat stress than C. cadmia, by increasing the expression of photosynthesis-related genes in the early stage of heat stress. It increased the excitation energy transferred to the PSII core complex and promoted the increase of electron transfer efficiency. But continuous heat stress will lead to a decrease in the chlorophyll content and net photosynthetic rate.

In summary, these investigation results indicated C. crassifolia and C. cadmia exhibited different photosynthetic characteristic, metabolic characteristics, antioxidant system, and gene expression patterns, which were related to their suitable living environment and genetic evolution. And we found that the photosynthetic system and enzymatic system may be the key links in the response to heat stress of C. crassifolia and C. cadmia, respectively. The hypothesis will be tested in future work. This study will pave the way to research the response and tolerance molecular mechanisms in clematis under heat stress.

**DATA AVAILABILITY STATEMENT**

The original contributions presented in the study are included in the article/Supplementary Material, further inquiries can be directed to the corresponding author.

**AUTHOR CONTRIBUTIONS**

QH performed the experiments, analyzed the data, and completed the manuscript. RQ and YZ helped to perform the experiment. XZ and XM revised the manuscript. JZ approved the completed manuscript.
