Abstract

Background: The coagulation factors (F)V and VIII are homologous proteins that support hemostasis through their regulation of FX activity. Hemophilia A (HA) patients have reduced FVIII activity and a prolonged bleeding time that is corrected through the administration of exogenous FVIII. Around one-third of severe HA patients develop FVIII neutralizing antibodies, known as “inhibitors,” which neutralize FVIII activity and preclude them from further FVIII therapy.

Objectives: We hypothesized that, based on the degree of homology between FV and FVIII (~40%), FVIII-neutralizing antibodies could cross react with FV. To test this hypothesis, a panel of recombinant, patient-derived, FVIII-neutralizing antibodies were screened for cross-reactivity against FV.

Methods: Factor V and FVIII activity was measured using one-stage clotting assays; structural analysis was carried out using a structural approach.

Results: We detected FV neutralizing activity with the anti-FVIII A2 domain antibody NB11B2. Because this antibody was derived from an HA inhibitor patient, FV-neutralizing activity was then evaluated in a number of HA inhibitor patient plasma samples; nine alloimmune samples had FV-neutralizing activity whereas no FV neutralizing activity was found in the two autoimmune samples available. We next examined the degree of surface homology between FV and FVIII and found that structural similarity could explain the cross-reactivity of the anti-A2 antibody and likely accounts for the cross reactivity we observed in patient samples.

Conclusions: Although this novel observation is of interest, further work will be needed to determine whether FV neutralization in HA patient samples contributes to their bleeding diathesis.

coagulation, coagulation factor V, coagulation factor VIII, FVIII inhibitors, hemostasis
1 | INTRODUCTION

Coagulation factors VIII (FVIII) and V (FV) share significant similarity with regard to structure and function. They are both large, Ca\(^{2+}\)-dependent plasma glycoproteins secreted as single inactive polypeptide chains that function as nonenzymic cofactors for serine proteases. FV and FVIII are proteolytically cleaved into heavy and light chains that are noncovalently associated by a Ca\(^{2+}\) ion. A summary of the similarities between FV and FVIII (and the related ceruloplasmin) is in Table 1.

Hemophilia A (HA) is a rare bleeding disorder that can be congenital or acquired. HA patients lack functional FVIII and are given exogenous FVIII products to restore hemostasis. A complication of congenital hemophilia is the alloimmune response to FVIII biotherapeutics and the development and circulation of FVIII-neutralizing antibodies that preclude these "inhibitor" patients from further treatment with FVIII. Because of the structural similarity between FVIII and FV, we hypothesized that there may exist some cross reactivity between the FVIII-neutralizing antibodies in HA inhibitor patient and FV.

A recombinant anti-FVIII antibody panel, described previously, was used to test the novel research hypothesis that FVIII-neutralizing antibodies can cross react with and neutralize FV owing to the high degree of homology that exists between these two proteins.

2 | MATERIALS AND METHODS

2.1 | Recombinant FVIII antibodies

In brief, the variable domains of heavy or light chain of patient-derived FVIII-neutralizing antibodies were cloned into an IgG4 framework and expressed in Chinese hamster ovary cells as recombinant antibodies. A full characterization of these antibodies has been described previously.

| TABLE 1 | Comparison of coagulation FV and FVIII and the related ceruloplasmin |
| Feature | FV | FVIII | Ceruloplasmin |
| Synthesis (as inactive precursor) | Liver > endothelial cells > megakaryocytes - also in platelet alpha granules | Liver > endothelial cells > megakaryocytes (also in platelet alpha granules) | Liver |
| Plasma concentration | 10 µg/ml (18) | 0.1–0.2 µg/ml (19) | 200–350 µg/ml |
| Structure | A1 - A2-B-A3-C1-C2 | A1-A2-B-A3-B-C1-C2 | A1-A2-A3 |
| Size | Heavy chain = 709 aa, 150 kDa | Heavy chain = 740 aa | Light chain = 684 aa |
| Cations | Ca\(^{2+}\), Zn\(^{2+}\) | Ca\(^{2+}\), Zn\(^{2+}\) | Six Cu\(^{2+}\) per monomer |
| Proteolysis | Thrombin (FXa and plasmin) cleaves FV | Thrombin sites 391/392, 759/760, 1332/1333, 1667/1668, 1708/1709 | None\(^a\) |
| Main function | FV increases FXa activity towards prothrombin (300 000-fold over FXa alone) to increase the efficiency of thrombin generation | FVIII increases FIXa activity -10 000-fold | Copper carrying, iron metabolism (ferroxidase) |
| Sulfation | Essential for efficient proteolytic cleavage by thrombin and activation | Sulfation at Tyr1699 is essential for VWF binding | None\(^a\) |
| Inactivation | aPC | aPC | |
| Signal peptides | 28 aa | 19 aa | 19 aa |
| Glycosylation | Extensive N- and O-linked glycosylation | Extensive N- and O-linked glycosylation | Six N-linked modification |

2.2 | Patient samples

Patient plasma samples from congenital (alloimmune) and acquired (autoimmune) patients were sourced from the archive at the Oxford Haemophilia Centre.

2.3 | Measurement of FV activity by prothrombin time (PT) assay

Recombinant antibodies were diluted in TBS buffer to 10× final concentration before being added (1/10) to FVIII-deficient plasma (F8DP, Siemens), which served as the FV source, and incubated for 2 h at 37°C. Prothrombin time was measured on an ACL Top 550 blood analyzer. Siemens Innovin reagent was reconstituted and stored according to the manufacturer’s instructions. Patient plasma samples were either diluted in 4% human serum albumin or used neat, added 50:50 with F8DP (Siemens) as the source of FV, and incubated for 2 h at 37°C. Patient samples were then assessed for PT using Siemens Innovin reagent and FV-deficient plasma (Siemens) on a Sysmex CS5100 blood analyzer. This in vitro assay, like the one-stage clotting assay used to measure FVIII activity, is a turbidimetric endpoint assay where the time taken to clot is converted to % FV activity using a standard curve.

2.4 | Calculating Bethesda titer

The FVIII-neutralizing activity of FVIII-neutralizing antibodies is reported in Bethesda units (BU/ml) (Bethesda titre) using the equation that follows. It is important that one chooses the dilution factor of patient plasma that gives closest to a 50% reduction in residual FVIII activity (ideally between 25% and 75%) to calculate the Bethesda titer. The higher the Bethesda titer, the more potent the FVIII neutralizing activity is.

\[
\text{Bethesda titer (BU/ml)} = \left( \frac{\log \left( \frac{100}{\% \text{ residual FVIII activity}} \right)}{\log(2)} \right) \times \text{dilution factor}
\]

2.5 | FV modelling

A structure for FV was modelled using the RaptorX software. The heavy and light chains were processed separately, and, among the RaptorX database, chains A and B of pdb (Protein Data Bank) 4BDV were identified as suitable templates for the homology modelling, respectively. This confirms the similarity between FV and FVIII because pdb 4BDV is the crystal structure of a truncated B-domain human FVIII. Modeller 9.24 was used to finally build the three-dimensional models for FV light and heavy chains. FV structures were then aligned to pdb 4BDV using the MultiSeq environment, as implemented in VMD. More specifically, the STAMP algorithm was used for alignment, and the root mean square deviation (RMSD) and Q_{ih} (QH ranges from 0 to 1 where QH = 1 refers to identical proteins)

10 values were used as indicators of structural similarity. FV pdb files are provided as Appendices S1 and S2.

2.6 | Statistical analysis

The data in Figure 1A were analyzed by two-way analysis of variance using multiple comparisons analysis with Tukey correction; p values of <.001 are shown with a double asterisk, whereas <.05 are shown with a single asterisk.

3 | RESULTS AND DISCUSSION

3.1 | Recombinant, patient-derived FVIII neutralizing antibodies inhibit FV

To begin, PT was used to measure and quantify FV activity. As shown in Figure 1A, NB11B2 reduced FV activity at 1 µM and 0.3 µM, indicating that cross reactivity of this antibody with FV is possible. NB11B2 is an anti-A2 domain antibody originally derived from an HA patient antibody isolated more than a decade ago. Although it is interesting that recombinant NB11B2 can neutralize FV activity when spiked into F8DP, whether FV neutralization would have been detectable in plasma samples from this patient is unknown; NB11B2 has an IC_{50} of 0.0001 µM for FVIII, so this interaction would likely dominate in vivo. To investigate FV neutralization in FVIII inhibitor patient samples, PT was initially measured in three alloimmune HA inhibitor patient plasma samples. These samples had FVIII Bethesda titers of 6 BU/ml, 11 BU/ml, and 115 BU/ml (the latter diluted to ~30 BU/ml), designated A, B, and C, respectively. NB11B2 (at a Bethesda titer of ~50 BU/ml) was included as a positive control; concentration-dependent prolongation of PT (presented as % residual FV activity) was detected in all three patient samples (Figure 1B [raw data] and Figure 1C [transformed data]). To quantify the FV-neutralizing activity, an FV Bethesda titer was calculated using the equation that is used to calculate FVIII Bethesda titers, substituting % residual FV activity for % residual FVIII activity. The FV Bethesda titer of A was 0.6 FV BU/ml, B had FV Bethesda titer of 0.2 FV BU/ml, and C diluted to 30 FVIII BU/ml had a FV Bethesda titer of 0.3 BU/ml. It was surprising to note that FV-neutralizing activity was detectable in all three patient samples, and we decided to assess additional samples, including two derived from acquired HA inhibitor patients. As shown in Figure 1D, mild to moderate FV-neutralizing activity was detected in all nine alloimmune HA inhibitor patient samples. These samples were then aligned to pdb 4BDV using the MultiSeq environment, as implemented in VMD. More specifically, the STAMP algorithm was used for alignment, and the root mean square deviation (RMSD) and Q_{ih} (QH ranges from 0 to 1 where QH = 1 refers to identical proteins)
HA patients remains to be determined. The PT assay measures clotting time initiated by the extrinsic coagulation pathway. Although not a direct measure of FV activity, the number of molecules that could underpin the observations in this study are limited to tissue factor, FVII, FX, and FV. This leads us to conclude that the increase in PT observed with the FVIII-neutralizing antibodies is likely due to FV neutralization, owing to the considerable homology between FV and FVIII. To gain further insight into these experimental findings, we next evaluated whether there was a structural basis for our observations. X-ray crystallography data are available for FVIII but the structure for FV has only been partially solved. A structural approach was therefore used to generate a novel FV structure that...
could be used to compare the regions of FV and FVIII that correspond to the epitopes of the recombinant FVIII-neutralizing antibodies used in this study (Figure 1A).

3.2 | Structural similarity between FVIII and FV underpins FV cross reactivity

Using the protein structure prediction server RaptorX, which selects structural templates for a "query" protein sequence, the structural similarity between FV and FVIII was investigated. FVIII and FV were aligned using the STAMP algorithm, which works by minimizing the $\alpha$ distance between the aligned residues from each molecule (FV in red, FVIII in black). A score of 468.7 (range, 1–709) and a $p$ value of 1.314e−40 was obtained for the FV heavy chains modelled against the chain A of pdb 4BDV, indicative of a good quality model ($p$ values <10−3–10−4 are generally desired). The only exception was Pro 686-Arg 737, which was omitted from the final structure because of poor fit. FV light chains modelled against chain B of pdb 4BDV had a score of 575.5 (range, 1–651) and the $p$ value was 4.652e−43, which again was indicative of good-quality modelling across the entire domain. Indicators of the final model quality, including alignment score and $p$ value, were favorable (Figure 2). This novel structure was then used to evaluate the structural similarity between FVIII and FV.
the degree of structural similarity between FV and FVIII to see whether it provided a rational basis for the cross reactivity that was observed in patient samples. The model was also used to evaluate the degree of similarity between epitopes to which the recombinant antibodies bind, as the epitopes are known. The RaptorX-generated FV structure was aligned with FVIII (4BDV) using the STAMP algorithm (Figure 2A) and the Q_{H} parameter used to identify areas of similarity (blue – Q_{H} = 1) and dissimilarity (red – Q_{H} < 0.3; Figure 2B). FV surface representations are also shown in Figure 2C (front) and Figure 2D (back) to highlight regions of similarity (gray) and dissimilarity (red) to FVIII. The prevalence of gray visually confirms the high degree of similarity between FV and FVIII and quantification using the RMSD and Q_{H} confirmed the model was of good quality; structural conservation between FV and FVIII is 87%–88%. This degree of similarity supports the level of cross reactivity that was observed in patient samples. Furthermore, the epitope reported for the parent antibody from which NB11B2 was derived maps broadly to FVIII residues 379–456 (A2 domain, Figure 2E), which display significant similarity in this FV model, and likely account for its cross reactivity with FV.

With regard to the recombinant antibodies that lacked cross reactivity, their epitopes lie in areas of the FVIII molecules that lack similarity to FV (regions of FV showing the lowest similarity to FVIII are summarized in Table 2). For example, the FVIII C1 “spike” K2092-F2093 epitope for NB33 is absent from our FV model (it maps into residues Y1984-L1985 in FV). Furthermore, the lack of FV neutralization by NB2C11 also fits with this model: X-ray crystallography studies identified the C2 domain spike M2199-F2200 as supporting the FVIII-antibody interaction and in FV, the corresponding C2 spike instead comprises two sequential tryptophan (W2091-W2092, which also lie in a region of high dissimilarity; see Table 2) residues, explaining the lack of cross reactivity. For NB41, its epitope was mapped to the FVIII a3-A3-C1 region and defined as R1803-K1818 and in an area described as dissimilar to FV (residues K1679-E1696 of FV in this model; see Table 2). Finally, NB2E9 is derived from a patient that neutralized wild-type exogenous FVIII, but not their endogenous FVIII, which had a mutation at R2150. A second residue, E2066, is also implicated in binding of this antibody and is positioned in a solvent-facing C1 loop. In this FV model, the corresponding R2150 aligns well (to R2042 in FV), but the residue corresponding to E2066 (E1951 in FV) resides in a much larger loop that takes up considerably more space (Figure 2F) and may occlude R2042 corresponding to R2150 in FVIII, accounting for the lack of neutralization. To summarize, by using this model to systematically evaluate the recombinant FVIII-neutralizing antibody epitopes, it was possible to identify a structural basis for the experimental observations of this study. NB11B2 is the only recombinant antibody in this panel that increased PT and whose epitope could be mapped to an area of significant similarity, indicating a structural basis for the cross reactivity observed.

4 | CONCLUSION

We report here for the first time that FVIII-neutralizing antibodies from alloimmune (but not autoimmune) HA inhibitor patients exhibit FV-neutralizing activity in the PT assay. Using a computationally derived structure for FV, structural characteristics were correlated with experimental data for the recombinant antibodies and a structural basis was found for these observations. Although these findings are novel and interesting, their bearing on the clinical presentation of HA patients remain to be seen: just because there is cross reactivity with FV does not mean that it will contribute to the clinical phenotype of the patient or necessitate any changes to how HA inhibitor patients are managed and treated. However, FV cross reactivity could account for disharmony between Bethesda titers and bleeding phenotype in some patients.
