Transgenic mice were generated with a human epidermal growth factor (EGF) receptor cDNA driven by the chicken β-actin gene promoter. One line (AE24) that exhibited a unique expression pattern in which dramatically elevated levels of EGF receptor RNA were found only in the testis was established, suggesting that the β-actin promoter was being influenced by an adjacent testis-specific enhancer. EGF receptor RNA was detected in primary spermatocytes, whereas the synthesis of receptor protein was restricted to elongate spermatids, indicating that transgene expression was under translational control. At spermiation, the EGF receptor was sequestered in residual bodies and excluded from mature sperm by a compartmentalization mechanism. About half of AE24 homozygous males were sterile because of sperm paralysis, whereas heterozygous males and females of either genotype were completely fertile. Electron microscopic analysis of sperm flagella from sterile AE24 homozygotes revealed an aberrant axonemal structure in which outer doublet microtubules were missing from the middle piece, resembling changes observed in the sperm of some infertile humans. Flagellar axonemal disassembly was observed in the vas deferens and epididymis but not in the testis, suggesting that outer doublets were assembled in a grossly normal manner but possessed a latent instability. These results demonstrate that in the AE24 mouse line the EGF receptor transgene was integrated into and inactivated an endogenous autosomal gene, causing sperm flagellar axonemal disruption and male sterility.

[Key Words: Flagellar microtubule, recessive mutation, sterility, testis, transgenic, translational control]

Received April 11, 1991; revised version accepted June 3, 1991.

Mammalian spermatogenesis consists of a complex series of biochemical and morphological alterations culminating in the generation of mature haploid spermatozoa (Hecht 1986; Handel 1987). The spermatogenic process can be subdivided into three main phases: mitotic renewal of germ-cell spermatogonia, meiotic reduction division of spermatocytes, and differentiation of spermatids into spermatozoa during spermiogenesis. Some understanding of these events has come from a genetic analysis of heritable defects in fertility. However, in mice, virtually every spontaneous mutation associated with male sterility that has been described also causes pleiotropic pathologic effects (for reviews, see Handel 1987; Green 1989). These mutations are usually identified by phenotypes unrelated to reproductive capabilities, and mutations affecting only male fertility are rarely detected. The expression of these other pathologic phenotypes makes the determination of the specific effect of a given gene on sperm structure and/or function problematic.

The ability to generate and study genetic mutations in mice has been greatly enhanced by the advent of transgenic technology. Although most transgenic mice created by the microinjection of DNA into one-cell mouse embryos have been used to explore the dominant effects of transgene expression, much information has also been gleaned from the study of insertional mutations resulting from random transgene integration (e.g., see Costantini et al. 1989; Shawlot et al. 1989; Woychik et al. 1990; Xiang et al. 1990), including mutations associated with

spermatogenesis and male sterility [Krulewski et al. 1989; Gordon et al. 1990; MacGregor et al. 1990]. Here we report the creation of a transgenic mouse line with a sterile male recessive mutant phenotype resulting from the integration of an epidermal growth factor (EGF) receptor fusion gene. The EGF receptor mediates the mitogenic potential of specific growth factors, including EGF and transforming growth factor α (TGF-α), and triggers a cascade of biochemical events leading to cellular proliferation [for a review, see Merlino 1990]. To determine the consequences of overexpression of the EGF receptor in a wide range of tissue types, we generated transgenic mice in which the expression of a human EGF receptor cDNA was driven by the chicken β-actin gene promoter.

In one line of these transgenic mice (AE24), an extremely high level of the EGF receptor was detected predominantly in late spermatids of the testis. Furthermore, the expression of the EGF receptor transgene was transcriptionally regulated. The creation of homozygous AE24 mice uncovered an insertional mutation in an endogenous gene causing sperm paralysis and male sterility but no other abnormal phenotypes. This communication describes the characterization of this transgenic mouse line and its mutant phenotype.

Results

Generation of EGF receptor transgenic mice

An EGF receptor expression vector consisting of 0.34 kbp of the chicken β-actin promoter, 4.06 kbp of the human EGF receptor cDNA, and a 0.4-kbp polyadenylation signal from the Abelson murine leukemia virus (MuLV) long terminal repeat (LTR) was made. This expression vector was highly active when transfected into NIH-3T3 cells, as judged by immunofluorescence with a human-specific EGF receptor monoclonal antibody (data not shown).

A 4.95-kbp PvuI–HindIII β-actin–EGF receptor fusion gene fragment (Fig. 1A) was microinjected into outbred CD1 one-cell mouse embryos. Six founder transgenic mice were generated. Two founders did not transmit the transgene through the germ line, and one founder possessed two distinct sites of transgene integration that were genetically segregated to create low-copy (AE24) and high-copy (AE24HC) transgenic mouse lines. Extensive examination of the AE24 genomic DNA revealed that a single copy of the transgene was present per haploid genome (Fig. 1C) and that the EGF receptor cDNA was structurally intact (data not shown).

Unique testicular overexpression of the EGF receptor transgene

To determine general patterns of transgene expression in β-actin–EGF receptor mice, we isolated RNAs from representative tissues obtained from the F1 progeny of three lines of mice and analyzed them by a variety of techniques (Table 1). The results demonstrated that the levels of EGF receptor RNA were dramatically elevated in the testis of line AE24 but were undetectable, low, or moderate in all other tissues examined. These results suggest that the pronounced testicular expression observed in line AE24 was unique, integration site specific, and not due solely to the presence of the chicken β-actin promoter. This conclusion was supported by expression data from two other lines of mice that bore unrelated transgenes driven by the same chicken β-actin promoter and that differed from each other and from the three EGF receptor transgenic mice (Table 1).

Northern blot hybridization was used to examine a complete panel of RNAs from the tissues of AE24 transgenic mice. Figure 2 shows that EGF receptor RNA was highly abundant only in the testis and present in very low levels in the liver (−25 times lower than in the testis) and in skeletal muscle (−60 times lower than in the testis). The size of the EGF receptor RNA in the testis of AE24 mice was determined to be 4.4–4.5 kbp, which was larger than the predicted size of 4.1 kbp. In the high-copy line AE24HC, only a trace expression was detected in the skeletal muscle and in the testis (−100 times lower than in the AE24 testis).

To quantify more precisely the level of EGF receptor RNA in the AE24 testis, we used an RNase protection assay. The signal obtained from AE24 testis RNA was compared with those obtained from RNAs isolated from human KB epidermoid carcinoma cells (containing 1 × 106 to 2 × 106 EGF receptors per cell) and from human A431 epidermoid carcinoma cells (possessing 3 × 106 EGF receptors per cell) [Xu et al. 1984]. <sup>a</sup>Summary of the activity of the chicken β-actin promoter in representative tissues of five lines of transgenic mice. One additional line was made (AE16) that exhibited no detectable transgene expression.

<sup>b</sup>The DNAs driven by the β-actin promoter include the human EGF receptor cDNA (EGFR), the bacterial chloramphenicol acetyltransferase gene (CAT), and the human MDR1 P-glycoprotein cDNA (MDR). CAT mice were analyzed by CAT protein assays and RNA primer extension, EGFR mice by RNase protection, Northern blotting, and primer extension; and MDR mice by slot and Northern blotting.

<sup>c</sup>(bm) Total bone in all mice except AM39, which was bone marrow; (br) brain; (h) heart; (i) intestine; (k) kidney; (li) liver; (lu) lung; (mu) leg skeletal muscle; (ov) ovary plus uterus in all mice except AC5 and AM39, which were ovary alone; (sp) spleen; (st) stomach; (te) testis.

<sup>d</sup>(-) Undetectable expression; (+) trace expression. Each additional + represents an approximately two- to threefold higher amount of measurable RNA. These values are based on examination of between two and five mice per line. Quantitation is less precise between lines due to variation in methods used to analyze expression.

<sup>e</sup>Data reproduced, with permission, from Galski et al. (1989).

shows that the signal, a 473-base protected RNA band, from AE24 testis was about three times higher than that obtained from KB cells and about one-tenth as strong as that obtained from A431 cells.

**Figure 2.** Northern blot analysis of EGF receptor transgene expression in tissues of AE24 homozygous mice. All samples contained 15 μg of total RNA, except for ovary plus oviduct, which contained 13.5 μg. RNAs were electrophoretically fractionated on 0.8% agarose, transferred to nitrocellulose, and hybridized with the <sup>32</sup>P-labeled pE7 insert. EGF receptor-specific RNA was visualized by autoradiography. Tissues: (Sa) Salivary gland; (Sp) spleen; (K) kidney; (Co) colon; (S) small intestine; (St) stomach; (Li) liver; (Pa) pancreas; (Lu) lung; (Br) brain; (Bo) bone marrow; (He) heart; (SV) seminal vesicle; (Ep) epididymis; (Te) testis; (Ut) uterus; (Ma) mammary gland; (Ov) ovary plus oviduct; (SM) skeletal muscle; (HCTe) testis from high-copy line AE24HC. (28S) Migration of the mouse 28S rRNA.

To determine whether transcription of the EGF receptor cDNA was being correctly initiated within the chicken β-actin promoter, we performed primer extension analysis with a human EGF receptor-specific 25-base oligonucleotide derived from the 5' end of the EGF receptor cDNA. Extension of this EGF receptor primer by reverse transcriptase resulted in a single intense band of 374 bases (Fig. 3B, lane 1), which is exactly the size expected if transcription was initiating from the chicken β-actin promoter (Fig. 3C). Larger bands were virtually undetectable by this assay, indicating that strong EGF receptor transcription was not due to initiation from an endogenous mouse promoter located in the 5'-flanking region of the transgene. Extension of human A431 RNA resulted in the generation of a prominent band of 443 bases (Fig. 3B, lane 3), corresponding to the location of the major start of transcription of the endogenous human EGF receptor gene.

**Postmeiotic synthesis of the EGF receptor**

Localization of the human EGF receptor protein within the AE24 testis was achieved with a human-specific EGF receptor monoclonal antibody in conjunction with immunoperoxidase and immunogold staining. Figure 4 shows that EGF receptors were present only in stage-specific germ cells within the seminiferous tubules. EGF receptors first appeared in elongate spermatids at stage 9 of spermatogenesis and reached a maximal level at stages 11 and 12 [Fig. 4A,G]. Higher magnification revealed that EGF receptors were located at the cell surface of late spermatids [Fig. 4I,J]. EGF receptors were concentrated within residual bodies at stage 8 [Fig. 4B] and were observed at the base of Sertoli cells by stage 9, probably
to EGF receptor-specific immunoperoxidase staining. Receptors were observed only at day 25 [Fig. 4F], and not at day 18 [Fig. 4E], consistent with the notion that EGF receptors were not synthesized during germ-cell mitosis or meiosis.

**Translational control of testicular EGF receptor expression**

In situ hybridization was used to determine the pattern of EGF receptor RNA accumulation in the AE24 testis. In contrast to the results of the protein localization studies, human EGF receptor RNA transcripts were widely distributed throughout the seminiferous tubules but were conspicuously absent from interstitial Leydig cells and Sertoli cells [Fig. 5C,D,H]. Grains were clearly seen over primary spermatocytes but not spermatogonial cells [Fig. 5H], indicating that the EGF receptor transgene was transcriptionally active during meiosis. In situ hybridization was also used to show that EGF receptor RNA transcripts were readily detectable in primary spermatocytes of the testis from juvenile 18-day-old AE24 transgenic mice [Fig. 5A,B,C], which do not possess differentiating spermatids. These results confirmed that human EGF receptor RNA was being made considerably earlier than EGF receptor protein and that the transgene was being regulated by a translational control mechanism reminiscent of the regulation of the expression of many endogenous mouse testicular genes [Hecht 1990].

**Sterility and aberrant sperm axoneme structure in homozygotes**

Taken together, these results suggest that the AE24 EGF receptor transgene was integrated into a testis-specific gene. To determine whether insertion of this transgene caused a mutation that would compromise spermatogenesis, we generated homozygous mice. Five homozygous female mice were identified by Southern blot hybridization and by analysis of litters from backcross matings to nontransgenic animals. All five appeared completely normal and were fertile. Twelve homozygous male mice were identified by quantitative Southern blot hybridization, but seven of these were found to be sterile. Examination of the spermatozoa from sterile AE24 homozygous mice revealed grossly atypical motility. Dark-field video microscopy demonstrated dramatic differences in sperm samples from fertile versus sterile animals. Sperm from all nontransgenic mice, as well as heterozygous and fertile homozygous transgenic mice, exhibited a normal rapid bending motion throughout the length of the sperm flagella [Fig. 6A]. In contrast, sperm from sterile homozygous transgenic mice possessed a rigid immobile middle piece, and rapid motion was restricted to the end piece and part of the principal piece [Fig. 6B].

Electron microscopy of sperm removed from the vas deferens of nontransgenic and sterile homozygous mice was used to determine the cause of their aberrant motility. Figure 7 shows a cross section through the middle piece of a typical nontransgenic sperm tail [A] and a sche-
Figure 4. Immunohistochemical localization of the human EGF receptor in the testes of adult (A–C, G–J), 25-day-old juvenile (F), and 18-day-old juvenile (E) AE24 transgenic mice and an adult nontransgenic CD1 mouse (D). Sections were made from either frozen (A–G) or paraffin-embedded (H–J) tissue. EGF receptor localization was done with either horseradish peroxidase (A–F, I) or colloidal gold (G–J) staining. The antibodies used were anti-EGFR–PE (A–G, I, J) or anti-PE alone (H). Magnifications: (A–F) 150× (bar, 27 μm); (G) 75× (bar, 53 μm); (H–J), 300× (bar, 13 μm).

A schematic representation of this normal pattern [A']. Non-transgenic axonemal microtubules are arranged so that nine peripheral or outer doublets surround a single central pair (9 + 2). In contrast, the majority of sperm from sterile homozygotes were missing some outer doublets and their corresponding associated structures, such as dynein arms and radial spokes, resulting in a 5 + 2 pattern in the middle piece [Fig. 7B, C].
Figure 5. (See facing page for legend.)
dense bodies usually remained intact in these abnormal sperm, it could be determined that the missing microtubule pairs were usually numbers 4-7 (cf. Fig. 7B with A'). Other bizarre arrangements of microtubules could be seen in the middle and principal pieces at a lower frequency, including extra and misplaced outer doublets [data not shown]. No overt abnormalities of the sperm head were observed.

Table 2 reveals that when middle-piece axonemes were analyzed from the sperm of three different sterile homozygotes, an average of 7% possessed the normal 9 + 2 pattern, whereas an average of 71% were arranged as 5 + 2. In contrast, the principal-piece axonemes of these abnormal sperm often possessed the 9 + 2 arrangement (Table 2). Although a smaller number of end-piece axonemes were analyzed, over 90% of these were determined to be normally configured. Sperm tails from nontransgenic and AE24 heterozygous and fertile homozygous mice were completely normal (Table 2). Furthermore, cilia lining the bronchioles of sterile homozygous male mice also contained normal axonemes [data not shown].

To determine whether the gross abnormalities associated with immotile sperm axonemes were due to aberrant assembly or enhanced instability, we analyzed sperm from the vas deferens, caudal epididymis, caput epididymis and testis by electron microscopy. Figure 8 shows that although the vast majority of flagellar axonemes in the sperm from the vas deferens and epididymis possessed atypical microtubule patterns (usually 5 + 2 or 6 + 2), sperm flagellar axonemes in the testis were generally found to be normal. These results suggest that sperm axonemes are assembled in a grossly normal fashion but undergo extensive microtubule disruption and/or disassembly after spermiation.

Discussion

Translational control

In this report we describe the generation of a number of
transgenic mice bearing a human EGF receptor cDNA driven by the chicken β-actin promoter. One unique line (AE24) possessed extremely strong EGF receptor gene expression in the testis and weak or undetectable expression in all other organs, suggesting that the transgene was being influenced by an adjacent endogenous testis-specific enhancer. Expression of the human EGF receptor cDNA was regulated by a translational control mechanism, reminiscent of the regulation of testis-specific mouse genes such as protamine 1, protamine 2, and transition protein 1 (for review, see Hecht 1990). Human EGF receptor RNA was detected in spermatocytes and spermatids, whereas EGF receptor protein first appeared postmeiotically in late, elongate spermatids.

Recent evidence indicates that the 3'-untranslated region of mRNAs transcribed from testis-specific genes such as protamine 1 and protamine 2 contains sequences that are essential for translational control [Braun et al. 1989; Hecht 1990]. The fact that the EGF receptor transgene in AE24 mice is under translational regulation raises the possibility that transcription can continue through the polyadenylation signal of the LTR and terminate within the 3'-flanking region, thereby creating a novel hybrid RNA transcript possessing a powerful translational control signal. This notion is supported by the finding that the size of the transgenic EGF receptor RNA was greater than expected, despite transcription starting at the correct transgene promoter initiation site. Alternatively, translation could be influenced by the secondary structure of EGF receptor RNA sequences. For this issue to be resolved, the 3'-flanking region of the transgene integration site must be isolated and sequenced.

**EGF receptor transit and compartmentalization during spermiogenesis**

The human EGF receptor should serve as a useful marker in the analysis of the synthesis, processing, and degradation of membrane-bound cell surface proteins during spermatogenesis. The receptor was first detected at the cell surface of postmeiotic elongate spermatids and was
subsequently concentrated in residual bodies. EGF receptor-laden residual material was then phagocytosed by Sertoli cells. The receptor could not be detected on mature sperm, suggesting that during spermiogenesis a compartmentalization mechanism segregates EGF receptor-containing membranes into residual bodies and away from spermatozoa and supporting the idea that sperm membranes are highly specialized and are the product of extensive maturation-related processing (Friend 1989; Bearer and Friend 1990).

**Insertional mutagenesis and male sterility**

These results raise the possibility that the EGF receptor transgene was integrated directly into an important testis-specific gene. This notion was strongly supported by the discovery that homozygous AE24 male mice were frequently sterile, apparently because of microtubule aberrations in sperm flagellar axonemes, whereas axonemes of the bronchiolar cilia in these sterile male homozygotes were structurally normal. The endogenous gene could encode a highly expressed, haploid-specific axonemal protein or, alternatively, a protein that indirectly dictates axonemal stability.

Although it is possible that EGF receptor overexpression also contributed to the appearance of the sterile phenotype, the presence of a vast excess of EGF receptors during sperm formation cannot be sufficient to cause sterility because heterozygous AE24 male mice have always been found to be fertile (45 of 45 heterozygotes tested possessed normal sperm) despite possessing extremely high receptor levels. Heterozygous mice exhibited no obvious phenotypic alterations in the testis or in any other organ. The testis was also found to be phenotypically normal in doubly transgenic mice made by crossing AE24 with MT42 (data not shown), which overexpresses TGFα in many tissues, including the testis (Jhappan et al. 1990). Presumably, elongate spermatids are not affected by the presence of excess ligand or receptor because they are differentiated and are no longer capable of a proliferative response.

**Incomplete penetrance of the sterile phenotype**

Homozygous AE24 male mice exhibited incomplete penetrance with respect to the sterile phenotype. Of the 12 homozygous male mice generated by heterozygote matings, 7 were sterile and possessed aberrant sperm axonemes, whereas 5 were fertile and possessed normal sperm axonemes. The reason for the incomplete penetrance of this phenotype is not known. The existence of two linked insertion sites has been refuted by Southern blot analysis of transgene flanking regions (data not shown). There is substantial genotypic variability within the AE24 outbred line, which could lead to the independent assortment of secondary genetic elements affecting fertility. Expression of the sterile phenotype in male mice can be strictly dependent on genetic background, including sterility associated with the t complex, the hybrid sterility genes 1 and 2 [Hst-1 and Hst-2], and specific autosomal chromosomal translocations (Forejt and Ivanýi 1975; Forejt 1976; Olds-Clarke and McCabe 1982; deBoer 1986; Olds-Clarke 1988).

Preliminary analysis of F1 and F2 progeny generated from matings between five fertile homozygous AE24 male mice and five homozygous AE24 female mice corroborates the dependency on genetic background. Of 38 homozygous male pups tested to date, 74% (28) possess normal sperm but 26% (10) contain grossly aberrant sperm. Some mating combinations resulted in the generation of all fertile male mice, whereas others produced about half fertile male mice. These results suggest that the expression of a second unlinked gene can obviate the need for the normal endogenous gene product. The genetic rescue of paralyzed axonemes has been described in *Chlamydomonas* cilia and may also help explain reproductive variations among male mice possessing different t haplotypes (Huang et al. 1982; Handel 1987; Olds-Clarke 1988).

**Defective sperm motility and axoneme disruption**

Many mutations associated with defective male fertility caused by abnormal spermatogenesis have been described; however, these lines of mice are characterized by a constellation of phenotypic abnormalities (Handel 1987; Green 1989). In contrast, homozygous AE24 transgenic mice only expressed a sterile male phenotype. Furthermore, although most mutant mice with aberrant sperm tail structure also exhibit abnormal sperm head morphology (Handel 1987; Green 1989), the heads of homozygous AE24 spermatozoa appeared to be normal by light and electron microscopic examinations (data not shown).

The electron microscopic data presented in this report suggest that sperm flagellar axonemes are assembled appropriately and appear to be normal in the sterile homozygous testis but possess a latent instability and undergo microtubule disassembly upon release from Sertoli cells and/or entry into the epididymis. In certain t haplotypes and the Wobbler mutation (wr), sperm microtubules are also arranged in aberrant patterns in the vas deferens but appear to be normal in the testis (Dooher and Bennett 1977; Leestma and Sepsenwol 1980). The defective nature of these mutant sperm may become manifest in the epididymis because at this time they undergo dramatic changes in morphology and biochemistry and acquire motility (Hoskins and Vijayaraghavan 1990). Interestingly, sperm tail axonemes from both wr/ and wr and sterile AE24 mice usually contain the same microtubule pattern (5 + 2) and are missing the same outer doublets (4–7) (Leestma and Sepsenwol 1980).

Mutations leading to sperm paralysis and male sterility have been described in humans as well as in mice (Ryder et al. 1990). The best described disease is immotile-cilia [Kartagener's] syndrome, in which men suffer from chronic sinusobronchial infections and abnormal motility of both respiratory cilia and sperm flagella (Eliason et al. 1977). In this case, sperm flagellar outer doublet microtubules are normal, and paralysis is caused by
Merlino et al.

the absence of dynein arms [Eliasson et al. 1977]. However, a relationship between the loss of axonemal microtubule doublets and sterility has been established by Escalier and David [1984], who used quantitative ultrastructural analysis to study the ejaculates from 56 sterile men. They found that 43% [24] of the ejaculates contained sperm that were missing outer-doublet microtubules and corresponding peripheral junctions; and in over 90% [22] of these cases, doublets 4-7 were absent, resulting in an aberrant axonemal pattern identical to that seen in sperm axonemes from sterile AE24 homozygous mice [5+2]. The manifestation of male sterility in both humans and mice because of the loss of specific sperm tail outer doublets raises the possibility that the endogenous gene inactivated in line AE24 by insertion of the EGF receptor transgene possesses an important and conserved function in sperm motility. Identification of a gene whose function is restricted to spermato genesis should greatly aid in the molecular dissection of this complex process.

Materials and methods

DNA constructions

The DNA fragment used for microinjection is shown in Figure 1A. A 4.9-kbp XbaI–PvuI fragment containing 4.06 kbp of human EGF receptor cDNA (Merlino et al. 1985) and 0.4 kbp of the Abelson MuLV LTR polyadenylation signal (Smal–PvuI, Reddy et al. 1983) was removed pMMTV-EGFR (Clark et al. 1986) and ligated into the XbaI–HindIII site of pUC19 to generate plasmid pEGFR0. A 0.34-kbp SalI–SalI chicken β-actin promoter fragment was removed from pCAT (generously provided by B. Paterson, Quitschke et al. 1989), converted to XbaI by linker ligation, and inserted into the XbaI site of pEGFR0 in the correct orientation, creating plasmid pBa-EGFR. Plasmid pEGFR-RP was constructed for synthesizing riboprobes by inserting a 473-bp XbaI–PstI MMTV-EGFR fragment (EGF receptor cDNA from −158 to +314, where AUG is +1; Ishii et al. 1985; Merlino et al. 1985) into the XbaI–PstI sites of pGEM3 (Fig. ID).

DNA microinjection and generation of transgenic mice

Plasmid DNAs were prepared by standard CsCl centrifugation techniques. pBa-EGFR was digested with PvuI and HindIII to release the 4.95-kbp microinjection fragment [Fig. 1A]. DNA fragments, purified as described previously [Jhappan et al. 1990], were microinjected into the pronuclei of one-cell mouse embryos, isolated in Brinster’s BMMC-3 medium (GIBCO) from the outbred strain CD1 (Charles River) as described by Hogan et al. [1986]. Surviving embryos were transferred into CD1 pseudopregnant foster mothers. Southern blot analysis of tail genomic DNA [Hogan et al. 1986] was used to identify transgenic founders. The 2.4-kbp ClaI–ClaI insert from the EGF receptor cDNA-containing plasmid pE7 [Fig. 1B] was used as a hybridization probe [Xu et al. 1984; Merlino et al. 1985]. Homozygous mice were identified by quantitative Southern blot hybridization, and homozygosity was confirmed in fertile mice by backcrossing to nontransgenic animals.

Preparation and analysis of RNA

Total RNA was isolated from various mouse tissues as described previously [Jhappan et al. 1990]. Human EGF receptor-specific RNase protection assays were performed with a uniformly labeled riboprobe, made with the PvuII-linearized pEGFR-RP template plasmid, SP6 polymerase, and [α-32p]GTP as described by the manufacturer [Promega]. The 546-base RNA riboprobe was incubated overnight at 42°C with 15 μg of total RNA, and the resulting RNA hybrids were exposed to RNases A and T1 at 30°C for 1 hr. Under these conditions, the endogenous mouse EGF receptor was not detectable. Northern blot analysis was performed as described elsewhere [Xu et al. 1984; Merlino et al. 1985]. Blots were stripped and rehybridized with a γ-actin probe to quantify RNA. RNA sizes were determined by comparison with mouse rRNAs and an RNA ladder (Bethesda Research Laboratories). Primer extension analysis was carried out as described previously [Merlino et al. 1982; Johnson et al. 1988], except that the 25-base oligonucleotide EGF1R [Fig. 3] was hybridized to total RNA in 40% formamide, 0.4 M NaCl, 1 mM EGTA, and 40 mM PIPES [pH 6.4] at 42°C for 3 hr [Johnson et al. 1988]. Extended radiolabeled DNA and RNase-protected RNA fragments were visualized by urea–4% polyacrylamide gel electrophoresis and autoradiography.

In situ RNA hybridization

The hybridization procedure was a modification of that described by Nakamura et al. [1989]. Sections of paraffin-embedded testes were hybridized with 32P-labeled RNA transcripts synthesized from the linearized pEGFR-RP plasmid with SP6 and T7 polymerases to generate antisense and sense probes, respectively. Transcription conditions were those described by the manufacturer [Promega]. Hybridization was done at a probe concentration of 1.25 × 106 cpn/ml [10 μl per slide]. Slides were exposed to Kodak NTB-2 emulsion for 3–21 days.

Histology and immunocytochemistry

Staging of testicular cells was done as described by Russell et al. [1990]. Tissues from transgenic and normal mice were either frozen for the preparation of cryostat sectioning or fixed in formaldehyde. Cryostat sections were air-dried and fixed in acetone. All antibody incubations included 0.1% saponin, 4 mg/ml of normal goat globulin, and PBS. A mouse monoclonal antibody specific for the human EGF receptor [no. 528] was generously provided by J. Mendelson [Masui et al. 1984]. A conjugate [anti-EGFR–PE] of this antibody with Pseudomonas exotoxin [as a hapten] was the generous gift of J. Pastan and J. Batra [Batra et al. 1989]. The labeling sequence was as follows: anti-EGFR–PE at 1 μg/ml, rabbit anti-Pseudomonas exotoxin [anti-PE] [the generous gift of D. Fitzgerald and J. Pastan] at 2 μg/ml, and goat anti-rabbit immunoglobulin G conjugated with either horseradish peroxidase [5 μg/ml; Jackson ImmunoResearch] or 1 nm of colloidal gold [Janssen Auroprobe; 1:100 dilution]; labeling was done at room temperature for 60 min. Peroxidase-labeled sections were developed with diaminobenzidine [Sigma] and osmium tetroxide. Colloidal gold-labeled sections were developed with Intense [Janssen] silver enhancement for 25 min.

Observations of sperm motility

Male mice that mated to fertile nontransgenic female mice but produced no offspring were judged to be sterile. Suspensions of living sperm were placed under a coverslip in either PBS or Dulbecco’s culture medium and examined at room temperature by using phase-contrast microscopy and video recording. Selected images were photographed at ~100-msec intervals to produce the pictures shown in Figure 6.
Electron microscopy

Tissues and sperm pellets were fixed in 3% glutaraldehyde in PBS, treated with 1% osmium tetroxide, dehydrated in ethanol and propylene oxide, and embedded in Epon 812. Thin sections were stained with uranyl acetate and lead citrate and viewed with a Philips 400T electron microscope.

Acknowledgments

We thank Ira Pastan, Hitoshi Takagi, Michael Gottesman, Alfred Johnson, Paul Overbeek, Grant MacGregor, George Gerton, Norman Hecht, Mary Ann Handel, and Mark Johnson for useful discussions and/or reading of the manuscript. We thank Eugene Chu, Betty Lovelace, and Richard Sharf for technical assistance, Bruce Paterson for the chicken β-actin promoter, J. Batra for the antibody-toxin conjugate anti-EGFR-PE, and John Mendelson for the EGF receptor monoclonal antibody. In particular, we are indebted to Marvin Meistrich for assistance in the staging of testicular cell types and for many fruitful discussions.

The publication costs of this article were defrayed in part by payment of page charges. This article must therefore be hereby identified as belonging to the group of free access articles in this journal.
