ABSTRACT

We analyse the large-scale clustering in Fourier space of emission line galaxies (ELG) from the Data Release 16 of the Sloan Digital Sky Survey IV extended Baryon Oscillation Spectroscopic Survey. The ELG sample contains 173 736 galaxies covering 1170 deg$^2$ in the redshift range 0.6 < z < 1.1. We perform a BAO measurement from the post-reconstruction power spectrum monopole, and study redshift space distortions (RSD) in the first three even multipoles. Photometric variations yield fluctuations of both the angular and radial survey selection functions. Those are directly inferred from data, imposing integral constraints which we model consistently. The full data set has only a weak preference for a BAO feature (1.4σ). At the effective redshift $z_{\text{eff}} = 0.845$ we measure $D_V(z_{\text{eff}})/r_{\text{drag}} = 18.32^{+0.57}_{-0.62}$, with $D_V$ the volume-averaged distance and $r_{\text{drag}}$ the comoving sound horizon at the drag epoch. In combination with the RSD measurement, at $z_{\text{eff}} = 0.85$ we find $f\sigma_8(z_{\text{eff}}) = 0.289^{+0.085}_{-0.096}$, with $f$ the growth rate of structure and $\sigma_8$ the normalization of the linear power spectrum, $D_H(z_{\text{eff}})/r_{\text{drag}} = 20.0^{+2.4}_{-2.2}$ and $D_M(z_{\text{eff}})/r_{\text{drag}} = 19.17 \pm 0.99$ with $D_H$ and $D_M$ the Hubble and comoving angular distances, respectively. These results are in agreement with those obtained in configuration space, thus allowing a consensus measurement of $f\sigma_8(z_{\text{eff}}) = 0.315 \pm 0.095$, $D_H(z_{\text{eff}})/r_{\text{drag}} = 19.6^{+2.2}_{-2.1}$ and $D_M(z_{\text{eff}})/r_{\text{drag}} = 19.5 \pm 1.0$. This measurement is consistent with a flat $\Lambda$CDM model with Planck parameters.

Key words: galaxies: distances and redshifts – cosmology: observations – dark energy – distance scale – large-scale structure of Universe.

1 INTRODUCTION

Why the Universe expansion is accelerating has been one of the most pressing questions of cosmology in the last two decades. The Universe expansion history is mostly naturally probed through the properties of the large-scale structures. In particular, the distribution of galaxies as measured by spectroscopic redshift surveys can be studied through two types of clustering analyses, which we carry out in this paper. The first type of analysis relies on the baryon acoustic oscillation (BAO) feature (Eisenstein & Hu 1998) to measure the distance–redshift relation. The second type of analysis is based on galaxy peculiar velocities. Indeed, redshifts of galaxies are not only due to Hubble expansion but also depend on their peculiar velocities.

Thus, converting redshifts into comoving distances assuming only the former contribution leads to galaxy coordinates being biased along the line of sight (Kaiser 1987). As peculiar velocities trace the gravitational potential field due to matter, these so-called redshift space distortions (RSD) make clustering measurements a way to test gravity and to measure the matter content of the Universe.

In this work, we study the clustering properties of the emission line galaxy (ELG) sample, which is part of the extended Baryon Oscillation Spectroscopic Survey (eBOSS; Dawson et al. 2016) Data Release 16 (DR16; Ahumada et al. 2019) of the Sloan Digital Sky Survey IV (SDSS-IV; Blanton et al. 2017). ELG spectra were collected by the BOSS (Baryon Oscillation Spectroscopic Survey) spectrograph (Smee et al. 2013) located at Apache Point Observatory (Gunn et al. 2006), New Mexico.

This study is part of a coordinated release of the final eBOSS measurements, also including BAO and RSD in the clustering of...
luminous red galaxies (Bautista et al. 2020; Gil-Marín et al. 2020) and quasars (Hou et al. 2020; Neveux et al. 2020). An essential component of these studies is the construction of data catalogues (Lyke et al. 2020; Ross et al. 2020), mock catalogues (Lin et al. 2020; Zhao et al. 2020a), and N-body simulations for assessing systematic errors (Alam et al. 2020; Avila et al. 2020; Rossi et al. 2020; Smith et al. 2020). At the highest redshifts (z > 2.1), the coordinated release of final eBOSS measurements includes measurements of BAO in the Lyman α forest (du Mas des Bourboux et al. 2020). The cosmological interpretation of these results in combination with the final BOSS results and other probes is found in eBOSS Collaboration (2020).1 Multi-tracer analyses to measure BAO and RSD using LRG and ELG samples are presented in Wang et al. (2020) and Zhao et al. (2020b). Star-forming ELGs are an interesting tracer for clustering analyses. Indeed, the star formation rate increases up to z ~ 2, where red galaxies are rarer. Also, the strong emission lines, such as Hα or the [O ii] doublet, ease the redshift measurement – thus allowing reduced spectroscopic observing time. The eBOSS ELG sample, with 173 736 galaxies distributed in the redshift range 0.6 < z < 1.1 (effective redshift of \( z_{\text{eff}} = 0.845 \)), is the largest and highest redshift ELG spectroscopic sample ever assembled and the third one to be used for cosmology (Blake et al. 2011; Contreras et al. 2013; Okumura et al. 2016). The eBOSS ELG sample has already been used to study the evolution of star-forming galaxies (Guo et al. 2019) and the circumgalactic medium of ELGs (Lan & Mo 2018). Details about the eBOSS ELG target selection can be found in Raichoor et al. (2016, 2017). The DR16 ELG clustering catalogue is described in Raichoor et al. (2020), which also includes a measurement of the isotropic BAO feature in configuration space. Tamone et al. (2020) presents the RSD analysis in configuration space.

In what follows, we present and analyse the clustering of galaxies of the DR16 ELG catalogue in Fourier space. We perform a RSD measurement using the observed galaxy density field, and an isotropic BAO measurement after reconstructing the density field to remove non-linear damping of the BAO signal.

The RSD analysis of the observed galaxy power spectrum allows joint constraints to be derived on the product \( f(z)\sigma_8(z) \), and ratios \( D_{\text{norm}}(z)\delta_{\text{drag}}(z) \) and \( D_{\text{norm}}(z)\delta_{\text{drag}}(z) \), at the effective redshift of the sample \( z_{\text{eff}} \). In these combinations, \( f(z) \) is the logarithmic derivative of the linear growth factor with respect to the scale factor \( a = 1/(1 + z) \) (hereafter referred to as the growth rate of structure) and \( \sigma_8(z) \) is the amplitude of the linear matter power spectrum measured in spheres of radius 8 Mpc \(^{-1} \) at redshift \( z \). We also use \( D_{\text{norm}}(z) = cH(z) \), the Hubble distance related to the Hubble expansion rate \( H(z) \), \( D_{\text{norm}} = (1 + z)D_M(z) \), the comoving angular diameter distance related to the proper angular diameter distance \( D_A \) and \( r_{\text{drag}} \) the comoving sound horizon when the baryon-drag optical depth equals unity. The BAO only analysis is sensitive to \( D_{\text{norm}}/r_{\text{drag}} \), \( D_{\text{norm}}/r_{\text{drag}} \), or a combination of both terms. In this work, we measure the ratio \( D_{\text{norm}}/r_{\text{drag}} \) with the volume-averaged distance \( D_M(z) = (D_A(z)D_A(z))^{1/3} \).

The RSD model we use is based on state-of-the-art two-loop order perturbation theory to ensure reliable modelling of the power spectrum up to mildly non-linear scales. Besides the standard survey window function, we also model the radial integral constraint (RIC) generated by the survey radial selection function being estimated from observed data. We carefully review potential sources of systematic errors, and apply correction schemes after validation based on

---

1 A summary of all SDSS BAO and RSD measurements with accompanying legacy figures can be found at https://sdss.org/science/final-bao-and-rsd-m measurements/. The full cosmological interpretation of these measurements can be found at https://sdss.org/science/cosmology-results-from-eboss/.

2 POWER SPECTRUM ESTIMATION

In this section, we detail our measurements of the power spectrum multipoles of the galaxy density field in a periodic box (used in Section 5.2) and within a real, sky-cut geometry (used in Section 6 and beyond).

2.1 Periodic box

We define the density contrast:

\[
\delta_g(r) = \frac{n_g(r)}{\bar{n}_g} - 1, \tag{1}
\]

where \( n_g(r) \) is the galaxy density at comoving position \( r \), and \( \bar{n}_g \) its average over the whole box of volume \( V \). Taking the Fourier transform \( \delta_g(k) \) of this field, power spectrum multipoles are calculated as

\[
P_l(k) = \frac{2l + 1}{4\pi} \int d^2q \delta_g(k)\delta_g(-k)\mathcal{L}_l(\hat{k} \cdot \hat{n}) - P_{l,\text{noise}}(k), \tag{2}
\]

where \( \mathcal{L}_l \) is the Legendre polynomial of order \( l \) and \( \hat{n} \) the unit global line-of-sight vector, which we choose to be one axis of the box. The shot noise term is non-zero for the monopole only:

\[
P_{0,\text{noise}} = \frac{1}{\bar{n}_g}. \tag{3}
\]

We use the implementation of the periodic box power spectrum estimator in the PYTHON toolkit NYBODYKIT (Hand et al. 2018). The density contrast field \( \delta_g(r) \) in equation (1) is interpolated on a 512 \(^3 \) mesh following the triangular shaped cloud (TSC) scheme. In the following (see Section 5), the box size is 3000 Mpc \( h^{-1} \) and thus the Nyquist frequency is \( k_N \geq 0.5 h \text{ Mpc}^{-1} \), more than twice larger than the maximum wavenumber used in the RSD analysis \( k = 0.2 h \text{ Mpc}^{-1} \). We checked that using a 700 \(^3 \) mesh \( (k_N \approx 0.7 h \text{ Mpc}^{-1}) \) does not change our measurement in a detectable way. Then, the term \( \delta_g(k) \) in equation (2) is calculated with a fast Fourier transform (FFT) of the interpolated density contrast and the interlacing technique of Sefusatti et al. (2016) is used to mitigate aliasing effects.

The integral over the solid angle \( d^2q \) in equation (2) is performed in spherical shells of \( \Delta k = 0.01 h \text{ Mpc}^{-1} \), from \( k = 0 h \text{ Mpc}^{-1} \). The discrete \( k \)-space grid makes the angular mode distribution irregular
at large scales, an effect which we account for in the model (see Section 3.3).

### 2.2 Real survey geometry

Following Feldman, Kaiser & Peacock (1994, FKP) the power spectrum estimator of Yamamoto et al. (2006) makes use of the FKP field:

\[ F(r) = n_s(r) - \alpha_s n_c(r), \]  

(4)

where \( n_s(r) \) and \( n_c(r) \) denote the density of observed and random galaxies, respectively, at comoving position \( r \). Random galaxies come from a Poisson-sampled synthetic catalogue accounting for the survey selection function. Observed and random galaxy densities include weights, i.e. corrections for systematics effects and FKP weights (Feldman et al. 1994). The scaling \( \alpha_s \) is defined by

\[ \alpha_s = \frac{N_g}{\sum_{i=1}^{N_i} w_{g,i} N_{s,i}}, \]  

(5)

with \( N_g \), \( N_i \) and \( w_{g,i} \), \( w_{s,i} \) the number and weights of observed and random galaxies, respectively. Then, the power spectrum multipoles are given by Bianchi et al. (2015):

\[ P_\ell(k) = \frac{2\ell + 1}{\ell} \int \frac{d\Omega}{4\pi} F_0(k) F_\ell(-k) - P_\ell^{\text{noise}}(k), \]  

(6)

with

\[ F_0(k) = \int d^3 r F(r) \mathcal{L}_s(\hat{k} \cdot \hat{r}) e^{i k \cdot r}, \]  

(7)

following the same notations as in Section 2.1. In this estimator, we take for line-of-sight \( \hat{\eta} = \hat{r} \) where \( \hat{r} \) is the direction to the second galaxy of the pair. This approximation introduces wide-angle effects in the power spectrum multipoles as well as the associated window function. However, these effects have been shown to not impact current RSD and BAO studies significantly (Castorina & White 2018; Beutler, Castorina & Zhang 2019).

The normalization term \( I \) is given by

\[ I = \alpha_s \sum_{i=1}^{N_i} w_{s,i} N_{g,i}, \]  

(8)

and the shot noise, which only contributes to the monopole in a scale-independent way, is

\[ P_0^{\text{noise}} = \frac{1}{I} \left[ \sum_{i=1}^{N_i} w_{s,i}^2 + \alpha_s^2 \sum_{i=1}^{N_i} w_{g,i}^2 \right]. \]  

(9)

For the density \( n_{g,i} \), we take the redshift density \( n(z) \), computed by binning (weighted) data in redshift slices of \( \Delta z = 0.005 \) (see Section 6.1 and Raichoor et al. 2020).

We use the implementation of the Yamamoto estimator in the Python toolkit nbodykit (Hand et al. 2018) to measure power spectra. Again, the FKP field (4) is interpolated on a 512^3 mesh with the TSC scheme. Terms \( F_\ell(k) \) of equation (7) are calculated with FFTs and the interlacing technique of Sefusatti et al. (2016) is used to mitigate aliasing effects. Here we use a box size of 4000 Mpc h^{-1}, so the Nyquist frequency is \( k_N \approx 0.4 h \text{ Mpc}^{-1} \). We again checked that using a 700^3 mesh (\( k_N \approx 0.55 h \text{ Mpc}^{-1} \)) does not change our measurement significantly.

The integral over the solid angle \( d\Omega \) in equation (6) is also performed in spherical shells of \( \Delta \ell = 0.01 h \text{ Mpc}^{-1} \), starting from \( k = 0.0 h \text{ Mpc}^{-1} \), unless otherwise stated.

### 2.3 Fiducial cosmology

To obtain the FKP field as a function of comoving position \( r \) we turn galaxy redshifts into distances assuming a fiducial cosmology. This fiducial cosmology will be also used (unless otherwise stated) to compute the linear matter power spectrum for the RSD and BAO analyses in Section 3. For both purposes, we utilized the same fiducial cosmology as in BOSS DR12 analyses (Alam et al. 2017): \( h = 0.676, \Omega_m = 0.31, \Omega_L = 0.69, \Omega_b h^2 = 0.22, \sigma_8 = 0.80, n_s = 0.97, \sum m_{nu} = 0.06 \text{ eV} \). (10)

Within this fiducial cosmology, which will be used throughout this paper (unless otherwise stated), \( r_{\text{drag}} = 147.77 \text{ Mpc} \).

### 3 MODEL

In this section, we review the different ingredients of the RSD model (Sections 3.1–3.5) and the isotropic BAO template (Section 3.6), which will be used throughout this paper.

#### 3.1 Redshift space distortions

The RSD model we use follows closely that of Taruya, Nishimichi & Saito (2010), Taruya, Nishimichi & Bernard (2013), hereafter referred to as the TNS model, as used in Beutler et al. (2017b). The redshift space galaxy power spectrum is expressed as a function of \( k \) the norm of the wavenumber \( k \) and its cosine angle to the line-of-sight \( \mu \):

\[ P_g(k, \mu, \tau, \beta) = D_{\text{FoG}}(k, \mu, \tau, \beta) \left[ P_{g,\text{lin}}(k) + 2 f^2 \mu^2 P_{g,\text{sh}}(k) \right. \]

\[ \left. + f^2 \mu^2 P_{g,\text{bat}}(k) + b_1^2 \text{I}(k, \mu, \beta) + b_1^2 \text{II}(k, \mu, \beta) \right], \]  

(11)

with \( \beta = \beta_{\text{lin}} + b_1 \) and \( b_1 \) is the linear bias. We adopt a Lorentzian form for the Finger-of-God effect (Jackson 1972; Cole, Fisher & Weinberg 1995):

\[ D_{\text{FoG}}(k, \mu, \tau, \beta) = \frac{1}{1 + \left( k \mu \sigma_v \right)^2}, \]  

(12)

with \( \sigma_v \) the velocity dispersion.

Galaxy–galaxy and galaxy–velocity power spectra \( P_{g,\text{lin}}(k) \) and \( P_{g,\text{sh}}(k) \) are given by

\[ P_{g,\text{lin}}(k) = b_1 P_{b,\text{lin}}(k) + b_2 P_{b,\text{sh}}(k) \]

\[ + 2 b_1 b_2 \sigma_v^2(k) P_{\delta_b,\text{lin}}^2(k) + b_1^2 P_{b,\text{bat}}(k), \]

\[ + 2 b_2 P_{b,\text{sh}}(k) + b_1^2 P_{b,\text{sh}}^2(k) + N_g \]  

(13)

and

\[ P_{g,\text{sh}}(k) = b_1 P_{b,\text{sh}}(k) + b_2 P_{b,\text{sh}}(k) \]

\[ + b_1 b_2 \sigma_v^2(k) P_{\delta_b,\text{lin}}(k) + b_2^2 P_{b,\text{sh}}^2(k), \]

(14)

where one-loop bias terms \( P_{b,\text{lin}}(k), P_{b,\text{sh}}(k), \sigma_v^2(k), P_{b,\text{bat}}(k), \) and \( P_{b,\text{sh}}(k) \) are provided in McDonald & Roy (2009), Beutler et al. (2017b). In this paper, power spectra \( P_{b,\text{lin}}(k), P_{b,\text{sh}}(k), \) and \( P_{b,\text{sh}}(k) \) are computed using the射电plane (RegPT) scheme (Taruya et al. 2012). We compute the linear matter power spectrum \( P_{\text{lin}}^m(k) \) in the fiducial cosmology (10) (except otherwise stated) with the Boltzmann code CLASS (Blas, Lesgourgues & Tram 2011) and keep it fixed in the cosmological fits.

\(^2\text{Note that only } \Omega_m \text{ (and } \Omega_L \text{) matter for the redshift to comoving distance (in Mpc } h^{-1} \text{) conversion.}\)
Second and third-order non-local biases $b_{i2}$ and $b_{nal}$ are fixed assuming local Lagrangian bias (Baldauf et al. 2012; Chan, Scoccimarro & Sheth 2012; Saito et al. 2014):

\[ b_{i2} = -\frac{4}{7} (b_1 - 1), \quad (15) \]
\[ b_{nal} = \frac{32}{315} (b_1 - 1). \quad (16) \]

### 3.2 The distance–redshift relationship

The fiducial cosmology used to turn angular positions and redshifts into distances may differ from the underlying cosmology of the data (or mock) galaxy sample. This leads to distortions in the $(k, \mu)$ space which can be detected through the so-called Alcock–Paczynski (AP) test (Alcock & Paczynski 1979). We define the scaling parameters $(\alpha_r, \alpha_\perp)$ to relate the observed radial and transverse wavenumbers $(k_r, k_\perp)$ to the true ones $(k'_r, k'_\perp) = (k_r/\alpha_r, k_\perp/\alpha_\perp)$. In the $(k, \mu)$ space, the corresponding mapping $(k, \mu) \to (k', \mu')$ is given by Ballinger, Peacock & Heavens (1996):

\[
\begin{align*}
    k' &= \frac{k}{\alpha_r} \left[ 1 + \mu^2 \left( \frac{\alpha_r^2}{\alpha_\perp^2} - 1 \right) \right]^{1/2}, \\
    \mu' &= \frac{\mu \alpha_\perp}{\alpha_r} \left[ 1 + \mu^2 \left( \frac{\alpha_r^2}{\alpha_\perp^2} - 1 \right) \right]^{-1/2}.
\end{align*}
\quad (17) \quad (18)
\]

Then, the power spectrum multipoles including the AP effect are expressed as

\[
P_p(k) = \frac{2^{\ell + 1}}{2\ell \alpha_\perp^2} \int_{-1}^{1} d\mu P^\ell(k'(k, \mu), \mu'(\mu)) \mathcal{L}_\ell(\mu). \quad (19)
\]

In practice, the AP effect is mostly sensitive to the change in the position of the BAO feature imprinted in the power spectrum at $r_{\text{drag}}$, the comoving sound horizon at the redshift at which the baryon-drag optical depth equals unity (Hu & Sugiyama 1996). Thus, scaling parameters are related to the true and fiducial cosmologies (fid):

\[
\begin{align*}
    \alpha_r &= \frac{D_H(z_{\text{eff}})}{D_H(z_{\text{eff}})} r_{\text{drag}}^\text{fid}, \\
    \alpha_\perp &= \frac{D_M(z_{\text{eff}})}{D_M(z_{\text{eff}})} r_{\text{drag}}^\text{fid}.
\end{align*}
\quad (20) \quad (21)
\]

with $D_H(z_{\text{eff}})$ the Hubble distance and $D_M(z_{\text{eff}})$ the comoving angular diameter distance given at the effective redshift of the galaxy sample $z_{\text{eff}}$, the superscript fid denoting quantities in the fiducial cosmology. Note that the $\alpha_r$ and $\alpha_\perp$ dependence on $r_{\text{drag}}$ is an approximation, and assumes that the scale-invariant in the power spectrum on the distance–redshift relationship only comes from BAO. Including this dependence in the $(\alpha_r, \alpha_\perp)$ parameters makes the power spectrum amplitude rescaling in the AP transform (19) formally incorrect. We expect this effect to be small for cosmological models that also fit the Planck constraints of Planck Collaboration VI (2018), who robustly measured $r_{\text{drag}} = 147.09 \pm 0.26$ Mpc (from TT, TE, EE, lowE, CMB lensing), close to the value of our fiducial cosmology in equation (10), $r_{\text{drag}}^\text{fid} = 147.77$ Mpc. The impact of the fiducial cosmology on data cosmological measurements will be tested in Section 8.

### 3.3 Irregular $\mu$ sampling

Power spectrum multipoles are calculated on a discrete $k$-space grid (Section 2), making the angular modes distribution irregular at large scales. We account for this effect in the model using the technique employed in Beutler et al. (2017b) which weights each $(k, \mu)$ mode according to its sampling rate $N(k, \mu)$ in the $k$-space grid:

\[
    p_{\ell}^{\text{fid}}(k, \mu) = \frac{N(k, \mu)}{\int_0^1 d\mu N(k, \mu)} P_\ell(k, \mu). \quad (22)
\]

Though this correction should be applied after the convolution by the window function (discussed hereafter), as in Beutler et al. (2017b), for the sake of computing time we include it when integrating the galaxy power spectrum over the Legendre polynomials in equation (19). We checked that the impact of such a correction on the cosmological parameters measured on the eBOSS ELG data is of the order of $10^{-3}$, well below the statistical uncertainty.

### 3.4 Survey window function

The observed galaxy density is modulated by the survey selection function. The resulting window function effect is accounted for in the model using the formalism of Wilson et al. (2017), Beutler et al. (2017b), and correctly normalized following de Mattia & Ruhlmann-Kleider (2019). Indeed, because of the fine-grained veto masks of the eBOSS ELG survey and the conventional choice made to estimate the survey area entering the redshift density estimation, the value of $I$ in equation (8) used to normalize the power spectrum estimation in equation (6) is inaccurate. We thus use this value in the normalization of window functions in the model, so that $I$ divides both the power spectrum measurements and model, and compensate. Therefore, the estimation of $I$ does not impact the recovered cosmological parameters. Fig. 1 shows the window function multipoles of the EZ mocks (reproducing the eBOSS ELG sample, see Section 6.2): the monopole has a non-zero slope even below $\lesssim 5$ Mpc $h^{-1}$ due to the fine-grained veto masks. For comparison purposes, we also plot the window function without veto masks applied; in this case, the monopole stabilizes faster on small scales. The area entering the estimation of $I$ used to normalize the unmasked window function has been kept fixed to the masked case. Since veto masks remove more area in the South Galactic Cap (SGC) than in the North Galactic Cap (NGC, see Raichoor et al. 2017), the unmasked SGC window function is relatively lower than the masked case compared to NGC.

In Section 7, we further check that veto masks do not bias cosmological measurements with our treatment of the window function.

The window function convolution requires to perform Hankel transforms between power spectrum and correlation function multipoles. We use for this purpose the FFTLOG software (Hamilton 2000). As in Beutler et al. (2017b), we only consider correlation function multipoles $\xi_\ell(s)$ up to $\ell = 4$ in our calculations. We checked that adding $\xi_\ell(s)$ has a completely negligible impact on the model prediction.

### 3.5 Integral constraints

The mean of the observed density contrast $F(r)$ of equation (4) on the survey footprint is forced to 0, as imposed by the definition of $\alpha_r$ in equation (5), leading to a so-called global integral constraint (GIC), which we model following de Mattia & Ruhlmann-Kleider (2019).

Moreover, in this analysis, as well as in other BOSS and eBOSS clustering analyses (e.g. Ross et al. 2012; Gil-Marín et al. 2016; Beutler et al. 2017b), redshifts of the random catalogue sampling the selection function are randomly drawn from the data (following the
so-called shuffled scheme). As discussed in de Mattia & Ruhlmann-Kleider (2019), this leads to the suppression of radial modes and impacts the power spectrum multipoles on large scales. We will see in Section 7 that this effect, if not accounted for, would be one of the largest systematics in the eBOSS ELG sample. We thus model this effect following the prescription of de Mattia & Ruhlmann-Kleider (2019) by replacing the GIC by the radial one for observed data and approximate mocks using the shuffled scheme. The impact of the GIC and RIC on the power spectrum multipoles is shown in Fig. 2. One can alternatively try to subtract the effect of the RIC from the data measurement (see e.g. Wang et al. 2020).

Note that the integral constraint (IC) formalism will also be used to account for our mitigating angular observational systematics, as suggested in de Mattia & Ruhlmann-Kleider (2019) and detailed in Section 7.

### 3.6 Isotropic BAO

In this paper we perform an isotropic BAO measurement on the eBOSS ELG sample. We checked that the amplitude of the power spectrum measured at $k \simeq 0.1 \, \text{h} \text{Mpc}^{-1}$ on post-reconstruction mock catalogues (see Section 6.2) is roughly constant over $\mu$, suggesting that the BAO information is isotropically distributed. Thus, the monopole is optimal for single-parameter BAO-scale measurement, which can be used to constrain the following combination (Eisenstein et al. 2005; Ross, Percival & Manera 2015):

$$\alpha = \alpha_1^{1/3} \alpha_2^{2/3}. \quad (23)$$

To fit the isotropic BAO feature, we use the same power spectrum template (dubbed wiggle template) as in previous analyses of BOSS and eBOSS (e.g. Gil-Marin et al. 2016; Beutler et al. 2017a; Ata et al. 2018):

$$P(k,\alpha) = P_m(k) O_{\text{damp}}(k/\alpha), \quad (24)$$

where

$$O_{\text{damp}}(k) = 1 + [O(k) - 1] e^{-1 \frac{1}{\sigma_\nu^2} k^2}. \quad (25)$$

$O(k)$ is obtained by taking the ratio of the linear matter power spectrum $P_m(k)$ to the no-wiggle power spectrum of Eisenstein & Hu (1998), augmented by a five order polynomial term, fitted such that $O(k)$ oscillates around 1. We take

![Figure 2. Power spectrum multipoles (top: NGC, bottom: SGC; blue: monopole, red: quadrupole, green: hexadecapole) of the RSD model. The window function effect only is taken into account in continuous lines, and the additional impact of the GIC and RIC are shown in dashed and dotted lines, respectively. For this figure, we choose $f = 0.8$, $b_1 = 1.4$, $b_2 = 1$, $\sigma_v = 4 \, \text{Mpc} \text{h}^{-1}$.](https://example.com/figure2.png)
This is legitimate since broad-band terms typically absorb these monopole term only, since the power spectrum template is isotropic. This is accounted for according to Section 3.4 through the (dominant) isotropic; this is not an issue since the correction seen in the case of (Section 3.3) as the power spectrum template in equation (24) is found such that the BAO template equation (24) can reproduce the mean of the EZ mocks (see Section 6.2) within 10 per cent of the uncertainty on the data power spectrum measurement. To specify the BAO detection and for plotting purposes in Section 8.1, we will use the no-wiggle template obtained by removing the oscillation pattern in equation (24) (i.e. keeping only the \( P_{\text{nw}}(k) \) factor).

We cannot include a correction for the irregular \( \mu \) sampling (Section 3.3) as the power spectrum template in equation (24) is isotropic; this is not an issue since the correction seen in the case of the RSD model is very small.

We also neglect the ICs (Section 3.5), as their impact will be shown to be negligible in Section 7. The effect of the survey window function is accounted for according to Section 3.4 through the (dominant) monopole term only, since the power spectrum template is isotropic. This is legitimate since broad-band terms typically absorb these smooth distortions of the power spectrum. We checked that totally ignoring the window function effect leads to a negligible change of \( \approx 10^{-3} \) in the \( \alpha \) measurement with the eBOSS ELG data.

### 4 FITTING METHODOLOGY

This section details how the previously described RSD and BAO models are compared to the data to derive cosmological measurements.

#### 4.1 Reconstruction

For the isotropic BAO analysis, the galaxy field is reconstructed to enhance the BAO feature in its 2-point correlation function (Eisenstein et al. 2007). This step (partially) removes RSD and non-linear evolution of the density field. We follow the procedure described in Burden, Percival & Howlett (2015) and Bautista et al. (2018). We perform three reconstruction iterations, assuming the growth rate parameter \( f = 0.82 \) and the linear bias \( b = 1.4 \). The density contrast field is smoothed by a Gaussian kernel of width 15 Mpc h\(^{-1}\). The choice of these reconstruction conditions and the assumed fiducial cosmology were shown to have very small impact on the BAO measurements in Vargas-Magaña et al. (2018) and Carter et al. (2020).

In this paper, isotropic BAO fits are performed on both pre- and post-reconstruction monopole power spectra, while the RSD analysis makes use of the monopole, quadrupole and hexadecapole of the pre-reconstruction power spectrum. As we will see in Section 8, the posterior of the RSD only measurement is significantly non-Gaussian, making it hard to combine with the isotropic BAO posteriors. We thus also use jointly the above pre-reconstruction multipoles with the post-reconstruction monopole (taking into account their cross-covariance) to perform a combined RSD and isotropic BAO fit. Further use of this new combination technique can be found in Gil-Marín et al. (2020) and Zhao et al. (2021).

#### 4.2 Parameter estimation

In the RSD analysis, fitted cosmological parameters are the growth rate of structure \( f \) and the scaling parameters \( \alpha_\parallel \) and \( \alpha_\perp \). Since \( f \) is very degenerate with the power spectrum normalization \( \sigma_s \), we quote the combination \( f \sigma_s \). As discussed in Gil-Marín et al. (2020) and Bautista et al. (2020), we take \( \sigma_s \) as the normalization of the power spectrum at \( 8 \times \alpha \) Mpc h\(^{-1}\) (instead of 8 Mpc h\(^{-1}\)), with \( \alpha = \alpha_\parallel^{1/3} \alpha_\perp^{2/3} \) as measured from the fit. We emphasize that the quoted \( f \sigma_s \) measurement can be straightforwardly compared to any \( f \sigma_s \) prediction, as usual. The sensitivity of our RSD measurements on the assumed fiducial cosmology is discussed in Section 5.4. We consider four nuisance parameters for the RSD fit: the linear and second-order bias coefficients \( b_1 \) and \( b_2 \), the velocity dispersion \( \sigma_v \) and \( A_g = N_g / P_0^{\text{noise}} \), with \( N_g \) the constant galaxy stochastic term (see equation 13) and \( P_0^{\text{noise}} \) the measured Poisson shot noise (see equation 9). Again, \( b_1 \) and \( b_2 \) are almost completely degenerate with \( \sigma_v \), so we quote \( b_1 \sigma_v \) and \( b_2 \sigma_v \).

For the isotropic BAO fit, the fitted cosmological parameter is \( \alpha \). Nuisance parameters are \( B_{\text{nw}} \) and the broad-band terms \( (A_g)_{i \in [-2, 2]} \) in equation (26). These last terms are fixed by solving the least-squares problem for each value of \( \alpha, B_{\text{nw}} \). The non-linear damping scale \( \Sigma_{\alpha} \) is fixed using \( N \)-body simulations in Section 5.5.

For the combined RSD and post-reconstruction isotropic BAO fit, we use parameters from both analyses. We rely on equation (23) to relate \( \alpha \) from the isotropic BAO fit to the \( \alpha_\parallel \) and \( \alpha_\perp \) scaling parameters of the RSD fit. We fix \( B_{\text{nw}} \) to \( b_1 \alpha_\parallel \), as this choice introduced no detectable bias in the fits of the EZ mocks (see Section 7). The varied parameters are reported in Table 1.

The fitted \( k \)-range of the RSD measurement is 0.03–0.2 Mpc h\(^{-1}\) for the monopole and quadrupole and 0.03–0.15 Mpc h\(^{-1}\) for the hexadecapole. We choose such a minimum \( k \) to avoid large scale systematics and non-Gaussianity. For the isotropic BAO fit, we use the monopole between 0.03 and 0.3 Mpc h\(^{-1}\).

### 4.3 Likelihood

As is in some other eBOSS analyses (e.g. Bautista et al. 2020; Neveux et al. 2020; Raichoor et al. 2020), we use a frequentist approach to estimate the scaling parameter \( \alpha \) for the isotropic BAO analysis. Bayesian inference is used to obtain posteriors for the eBOSS ELG RSD (and RSD + BAO) measurements. For the sake of computing time, we use a frequentist estimate of the cosmological parameters

| Table 1. Varied parameters, and their priors in the case of the Bayesian inference (MCMC). Priors are all flat, with infinite bounds, except for those mentioned below. No MCMC is run for the BAO only analysis. In all cases (including MCMC), parameters \( (A_g)_i \in [-2, 2] \) are solved analytically (see the text). |
|---|---|---|
| RSD | BAO | RSD + BAO |
| Varied parameters | \( f, \alpha_\parallel, \alpha_\perp, b_1, b_2, \sigma_v, A_g \) | \( \alpha, B_{\text{nw}}, (A_g)_{i \in [-2, 2]} \) | \( f, \alpha_\parallel, \alpha_\perp, b_1, b_2, \sigma_v, A_g, (A_g)_{i \in [-2, 2]} \) |
| NGC/SOC specific | \( b_1, b_2, \sigma_v, A_g \) | \( B_{\text{nw}}, (A_g)_{i \in [-2, 2]} \) | \( b_1, b_2, \sigma_v, A_g, (A_g)_{i \in [-2, 2]} \) |
| Priors (MCMC) | \( f \geq 0 \), \( b_1 \geq 0 \), \( \sigma_v \geq 0 \) | | \( f \geq 0 \), \( b_1 \geq 0 \), \( \sigma_v \geq 0 \) |
from the $N$-body based and approximate mocks and to perform data robustness
tests.

In the frequentist approach, we perform a $\chi^2$ minimization using the
Minuit (James & Roos 1975) algorithm,\footnote{https://github.com/iminuit/iminuit} taking large variation
intervals for all parameters. We check that the fitted parameters do not
reach the input boundaries. Errors are determined by likelihood
profiling: the error on parameter $p_i$ is obtained by scanning the $p_i \rightarrow$
min$_{p_i} \chi^2(p)$ profile until the $\chi^2$ difference to the best fit reaches
$\Delta \chi^2 = 1$ (while minimizing over other parameters $p_j$).

In the case of $N$-body mocks with periodic boundary conditions
(see Section 5.2), we compute an analytical covariance matrix
following Grieb et al. (2016). In the case of data (see Section 6.1) or
approximate mocks (Section 5 or approximate mocks in Section 6), the power spectrum covariance matrix
is estimated from approximate mocks (lognormal, EZ, or GLAM-
QPM mocks). We thus apply the Hartlap correction factor (Hartlap,
Simon & Schneider 2007) to the inverse of the covariance matrix
measured from the mocks:

$$\Psi = (1 - D) C^{-1}, \quad D = \frac{n_b + 1}{n_m - 1}$$

with $n_b$ the number of bins and $n_m$ the number of mocks. To propagate
the uncertainty on the estimation of the covariance matrix, we rescale
the parameter errors (Dodelson & Schneider 2013; Percival et al.
2014) by the square root of

$$m_1 = \frac{1 + B (n_b - n_p)}{1 + A + B (n_p + 1)},$$

with $n_p$ the number of varied parameters and

$$A = \frac{2}{(n_m - n_b - 1)(n_m - n_b - 4)},$$

$$B = \frac{2}{(n_m - n_b - 2)(n_m - n_b - 4)}.$$ \hspace{1cm} (28)

When cosmological fits are performed on the same mocks used to
estimate the covariance matrix, the covariance of the obtained best
fits should be rescaled by

$$m_2 = (1 - D)^{-1} m_1.$$ \hspace{1cm} (31)

In Appendix A, we propose a new version of this formula, accounting
for a combined measurement of several independent likelihoods,
which we use when fitting both the NGC and SGC. The magnitude of the
rescaling (A22) is of order 5.5 per cent at most (for the combined
RSD + BAO measurements).

In the Bayesian approach, which we use to produce the posterior
of the eBOSS ELG RSD and BAO + BAO measurements, the uncertainty on the covariance matrix estimation is marginalized over
following Sellenkin & Heavens (2016):

$$\mathcal{L}(x^d|p) \propto \left\{ 1 + \frac{1}{n_m - 1} \left[ x^d - x^d(p) \right] C^{-1} \left[ x^d - x^d(p) \right] \right\}^{-\frac{1}{2}},$$

where we note the power spectrum measurements (data) $x^d$ and the model (theory) $x^d$ as a function of parameters $p$. The combined
NGC and SGC likelihood is trivially the product of NGC and SGC likelihoods.

Our posterior is the product of equation (32) with flat priors on all
parameters, infinite for all of them, except for $f$, $b_1$, and $\sigma_8$, which are lower bounded by 0 (see Table 1).

To sample the posterior distribution we run Markov chains Monte
Carlo (MCMC) with the package EMCEE (Foreman-Mackey et al.
2013). We run eight chains in parallel and check their convergence
using the Gelman–Rubin criterion $R - 1 < 0.02$ (Gelman & Rubin
1992).

5 MOCK CHALLENGE

In this section, we validate our implementation of the RSD TNS
model and isotropic BAO template (presented in Section 3) against
mocks based on $N$-body simulations, which are expected to more
faithfully reproduce the small-scale, non-linear galaxy clustering.
We estimate the potential modelling bias in the measurement of
cosmological parameters. We refer the reader to Alam et al. (2020)
and Avila et al. (2020) for a complete description of this mock challenge.

5.1 MultiDark mocks

A first set of mocks is based on the $z_{\text{snap}} = 0.859$ snapshot of the MultiDark simulation MDPL2 (Klypin et al. 2016) of volume
1 (Gpc/$h^3$) and 3840$^3$ dark matter particles of mass $1.51 \times 10^9 M_{\odot}/h^3$, run with the flat $\Lambda$CDM cosmology\footnote{https://www.cosmosim.org/cms/simulations/mdpl2/}:

$$h = 0.6777, \quad \Omega_m = 0.307115, \quad \Omega_b = 0.048206, \quad \sigma_8 = 0.8228, \quad n_s = 0.9611.$$ \hspace{1cm} (33)

Dark matter haloes were populated with galaxies following
two halo occupation distribution (HOD) models: a standard HOD
($SHOD$), and an HOD quenched at high mass ($HMQ$, see Alam et al.
2020 for details). Eleven types of mocks were produced for each
HOD; in addition to the baseline (type 1), these include 50 per cent
variations in the halo concentration in dark matter and the velocity
dispersion of satellite galaxies (types 2, 3, 4, and 5), a shift in the
position of the central galaxy (type 6) and assembly bias prescriptions
(types 7, 8, and 9). In the last two types of mocks (types 10 and 11),
galaxy velocities were upscaled (downscaled) by 20 per cent, for
which we thus expected a 20 per cent increase (decrease) of the $f_{\text{r3d}}$
measurement. The galaxy density reached $3 \times 10^{-3} / h$/Mpc$^3$, about
10 times the mean eBOSS ELG density, such that the shot noise
is very low.

We derived a covariance matrix from a set of 500 lognormal
mocks produced with nbodykit, in the MDPL2 cosmology of
equation (33), assuming a bias of 1.4 and with the same density of
$3 \times 10^{-3} / h$/Mpc$^3$. We checked that the agreement between
$N$-body based and lognormal mocks was satisfactory on the whole $k$-range
of the cosmological light.

Both $N$-body based and lognormal mocks were analysed with the fiducial cosmology of equation (10), as for the eBOSS ELG data. We thus accounted for the appropriate window function and GIC
effect (Section 3.5) in the model, and we included the correction for
the irregular $\mu$ distribution (Section 3.3) at large scales. As reported
in Alam et al. (2020, fig. 4), the fitted cosmological parameters
were found to be within 1$\sigma$ of the expected values, even for mocks
with rescaled galaxy velocities, where the offset in the fitted $f_{\text{r3d}}$
values corresponds to the 20 per cent offset in velocity. However,
the obtained uncertainties were only half of those expected with
the eBOSS ELG sample, which was not sufficient to derive an
accurate modelling systematic budget. We thus focused on larger
mocks.
and we only included the correction for the irregular \( \mu \) distribution (Section 3.5) at large scales. A Gaussian covariance matrix was calculated following Grieb et al. (2016) for each of these mocks, taking their measured power spectrum as input.

No evidence for an overall systematic bias of the model was found when analysing these mocks, as reported in Alam et al. (2020).

5.3 Blind OuterRim mocks

We participated in a blind mock challenge dedicated to the ELG sample (see Alam et al. 2020, section 8). For simplicity, only velocities and HOD parameters were changed, while the background cosmology was kept fixed. Therefore, only the value of \( f_{\text{rs}} \) was blind. 30 to 40 realizations for each of the six types of mocks (three for \( \text{SHOD} \) and \( \text{HMQ} \) HODs) were produced with a density of the order of the eBOSS ELG mean density \([\simeq 2 \times 10^{-4} \,(h/\text{Mpc})^3]\). The OuterRim boxes were analysed the same way as in Section 5.2. Though velocities were scaled by as much as 50 per cent, no significant systematic shift in \( f_{\text{rs}} \) could be seen, confirming the robustness of our RSD model.

The systematic uncertainties resulting from this blind mock challenge were derived in Alam et al. (2020, section 9): 1.6 per cent on \( f_{\text{rs}} \), 0.8 per cent on \( \alpha_v \), and 0.7 per cent on \( \alpha_\perp \). We do not scale these errors by a factor of 2 as in Alam et al. (2020), since we further take into account the effect of the fiducial cosmology in Section 5.4 in a conservative way.

5.4 Fiducial cosmology

As Hou et al. (2020), Neveux et al. (2020), Gil-Marín et al. (2020), and Bautista et al. (2020), we test the dependence of the measurement of cosmological parameters with respect to the cosmology – dubbed as template cosmology – used to compute the linear power spectrum for the RSD model \((P_\text{lin}(k))\), see Section 3.1). To this end, we reanalyse the first set of OuterRim mocks (types 1, 4, 5, and 6, with \( \text{SHOD} \) and \( \text{HMQ} \) HODs) presented in Section 5.2, but using different template cosmologies. We consider first the fiducial cosmology of the data analysis (10) and also scale each of the cosmological parameters \((h, \omega_{\text{CDM}}, \omega_b, \text{ and } n_s)\) of (34) by \pm 10 per cent to \pm 20 per cent (typically 30\sigma variations of Planck Collaboration VI (2018) CMB (TT, TE, EE, lowE, lensing) and BAO constraints).

Note that for simplicity we do not change the fiducial cosmology (34) used in the analysis (power spectrum estimation and Gaussian covariance matrix) and thus rescale the fitted \( \alpha_v \), \( \alpha_\perp \) accordingly to determine \( \sigma_8 \) as in Section 4.2.

Results are shown in Fig. 3. Scaling parameters are well recovered. The best-fitting \( f_{\text{rs}} \) value is primarily sensitive to the template \( h \) and \( n_s \) values. Taking the root mean square of the difference (averaged over all types, HODs, and lines of sight) to the expected values gives the following systematic uncertainties: 2.6 per cent on \( f_{\text{rs}} \) and 0.4 per cent on scaling parameters. Note that without the \( \sigma_8 \) rescaling described in Section 4.2 the systematic uncertainties related to the choice of template cosmology would have been twice larger for \( f_{\text{rs}} \).

We add the above uncertainties in quadrature to those derived in Section 5.3 to obtain the final RSD modelling systematics: 3.0 per cent on \( f_{\text{rs}} \), 0.9 per cent on \( \alpha_v \), and 0.8 per cent on \( \alpha_\perp \).

This systematic budget was consistently updated using our prescription for \( \sigma_8 \) discussed in Section 4.2 – leading to a minor relative decrease of 4 per cent on the systematics for \( f_{\text{rs}} \).
best fit and expected values gives a systematic uncertainty of the model. Taking the root mean square of differences between small dependence with the template cosmology, as also found. Results are shown in Fig. 4. The measured values in the rest of the paper, unless stated otherwise.

The grey shaded area represents an error of 0.5 per cent on $\alpha$ on either side of the reference value in the OuterRim cosmology.

5.5 Isotropic BAO

We also test the robustness of the isotropic BAO analysis with respect to variations in the HOD and template cosmology. Again, we consider the first set of OuterRim mocks (types 1, 4, 5, and 6, with SHOD and HMQ HODs) presented in Section 5.2, apply them reconstruction (with the parameters set in Section 4.1), and measure their power spectrum using the OuterRim cosmology (34).

Using the isotropic BAO model described in Section 3.6, we first find (with the OuterRim cosmology as template cosmology) a damping parameter $\Sigma$ fit of value of 8 Mpc $h^{-1}$ (4 Mpc $h^{-1}$) to fit the pre-reconstruction (post-reconstruction) power spectrum. We use these values in the rest of the paper, unless stated otherwise.

We then perform the post-reconstruction isotropic BAO fits with the different template cosmologies introduced in Section 5.4. Results are shown in Fig. 4. The measured $\alpha$ value shows very small dependence with the template cosmology, as also found in e.g. Carter et al. (2020). The same is true for the HOD model. Taking the root mean square of differences between best fit and expected values gives a systematic uncertainty of 0.2 per cent on $\alpha$, which we take as BAO modelling systematics.

In addition, in order to quantify how typical the data BAO measurements are (see Section 8.1), we generate accurate mocks designed to match the ELG sample survey geometry. An OuterRim box (satellite fraction of 0.14, no velocity bias) is trimmed to the eBOSS ELG footprint, including veto masks and radial selection function. We then cut six nearly independent mocks for NGC and SGC with three different orientations. The original box was replicated by 20 per cent to enclose the total SGC footprint. As the ELG density in the OuterRim box is much larger than the observed ELG density, we draw four disjoint random subsamples for each sky-cut mock. The number of galaxies in the mock samples match that of the data to better than 1 per cent. Then, we randomly generate 1000 fake mock power spectra following a multivariate Gaussian. The Gaussian mean comes from the pre- and post-reconstruction power spectrum measurements of the above sky-cut OuterRim mocks, and its covariance matrix is given by the baseline EZ mocks. These fake post-reconstruction power spectra will be used to quantify the probability of the BAO measurements of the data in Section 8.1.

6 DATA AND APPROXIMATE MOCKS

In this section, we briefly describe the eBOSS ELG sample and the approximate EZ and GLAM-QPM mocks used to produce the covariance matrix of the measured power spectrum multipoles and to assess the impact of observational systematics on the final clustering measurements.

6.1 Data

We use the ELG clustering catalogues from SDSS DR16 published in Raichoor et al. (2020). We refer the reader to that paper for a complete description of the different survey masks and weighting schemes adopted to account for variations of the survey selection function in the data.

Contrary to other BOSS and eBOSS surveys making use of the SDSS-I-II-III optical imaging data, ELG targets were selected from the Data Release 3 and 5 of the Dark Energy Camera Legacy Survey (DECaLS; Dey et al. 2019) in the grz bands (see Raichoor et al. 2017). DECaLS photometry, which is at least one magnitude deeper than the SDSS imaging in all bands, will be used by the next-generation survey Dark Energy Spectroscopic Instrument (DESI; Collaboration 2016). However, the homogeneity of the imaging quality over the eBOSS ELG footprint was not fully under control in this early version of DECaLS, a point we will further discuss below.

The footprint and redshift density of the eBOSS ELG survey are shown in Fig. 5. The eBOSS ELG sample selects star-forming ELGs in the redshift range 0.6 < z < 1.0 and within tiling chunks $eboss21$ and $eboss22$ in the SGC and chunks $eboss23$ and $eboss25$ in the NGC. The number of targets ($N_{\text{target}}$) and ELGs ($N_{\text{elg}}$) in the final clustering sample is given in Table 2.

Three types of weights are introduced to correct for variations of the selection function in the data. The systematic weight $w_{\text{sys, i}}$ corrects for fluctuations of the ELG density with imaging quality. The close-pair weight $w_{\text{cp, i}}$ accounts for fibre collisions. Finally, $w_{\text{comp, i}}$ corrects for redshift failures.

A synthetic (random) catalogue is built to sample the survey selection function of the weighted data. Angular coordinates of the synthetic catalogue are uniformly random, and random objects outside the footprint, including veto masks, are removed. Data redshifts are assigned to random objects, following the shuffled scheme proposed in Ross et al. (2012). The previously mentioned anisotropies of the DECaLS imaging quality induce fluctuations of the eBOSS ELG redshift density which shall be introduced in the synthetic catalogue (Raichoor et al. 2020). We found the main driver for these fluctuations to be imaging depth. We therefore assign data redshifts to randoms in three separate sub-regions (dubbed chunk $z$) of each tiling chunk defined according to their value of imaging depth. The depth-bins are chosen such that the redshift distribution is considered sufficiently (i.e. within shot noise and cosmic variance) constant within each chunk $z$. In the synthetic catalogue, $w_{\text{sys, i}}$ accounts for the tiling completeness while $w_{\text{cp, i}}$ and $w_{\text{comp, i}}$ are all set to 1. $w_{\text{sys, i}}$ is then scaled such that the weighted number of random objects and data objects match in each chunk $z$.

Each data and random object is weighted by the total weight $w_{\text{tot, i}} = w_{\text{FPK, i}} w_{\text{comp, i}}$ with $w_{\text{comp, i}} = w_{\text{sys, i}} w_{\text{cp, i}} w_{\text{comp, i}}$. Its completeness weight and $w_{\text{FPK, i}}$ the FKP weight:

$$w_{\text{FPK, i}} = \frac{1}{1 + n_{\text{d, i}} P_0},$$

$^a$Regions in which the fibre assignment (determining the positions of the plates and fibres) is run independently.
where we take \( P_0 = 4000 \, (\text{Mpc}/h)^3 \), close to the measured power spectrum monopole at \( k \simeq 0.1 \, h \, \text{Mpc}^{-1} \) (see Fig. 6). The redshift density \( n_g \) is calculated in each chunk by binning data weighted by \( w_{\text{comp},i,j} \) into redshift slices of size \( \Delta z = 0.005 \), starting at \( z = 0 \), and dividing the result by the comoving volume of each shell, assuming the fiducial cosmology of equation (10). The effective area used for the calculation is given by the number of randoms weighted by the tiling completeness in the final clustering sample divided by their original density (see Table 2 and Raichoor et al. 2020).

In order to match the definition used for other eBOSS tracers and analyses, the effective redshift \( z_{\text{eff}} \) of the ELG sample between \( 0.6 < z < 1.1 \) is calculated as

\[
z_{\text{eff}} = \frac{\sum_{i,j} w_{\text{tot},i} w_{\text{tot},j} (z_{g,i} + z_{g,j})}{2 \sum_{i,j} w_{\text{tot},i} w_{\text{tot},j}},
\]

where the sum is performed over all galaxy pairs between 25 and 120 \( \text{Mpc} \, h^{-1} \). We measure \( z_{\text{eff}} = 0.845 \) for the combined NGC and SGC (NGC alone: 0.849, SGC alone: 0.841). We checked that this result varies by less than 0.4 per cent when including pairs between 0 and 200 \( \text{Mpc} \, h^{-1} \). In Appendix B, we provide a definition of the effective redshift more specific to the power spectrum analysis, which quantitatively gives the same value as that adopted in equation (36). We also compute the effective redshift corresponding to the cuts \( 0.7 < z < 1.1 \), which will be used in Section 8: \( z_{\text{eff}} = 0.857 \) for the combined NGC and SGC (NGC alone: 0.860, SGC alone: 0.853). The typical variation (using equation (10)) corresponding to the \( \pm 0.8 \) per cent difference between the effective redshift of NGC and SGC is 0.2 per cent on \( D_M/r_{\text{drag}} \) and 0.6 per cent on \( D_M/r_{\text{drag}} \), small compared to the statistical uncertainty (see Section 8).

\[ h = 0.6777, \quad \Omega_m = 0.307115, \quad \Omega_b = 0.048206, \quad \sigma_8 = 0.8225, \quad n_s = 0.9611. \]

6.2 EZ mocks

The generation of EZ mocks is detailed in Zhao et al. (2020). The 1000 EZ mocks (NGC, SGC) are built from EZ boxes of side 5 Gpc \( h^{-1} \), with a galaxy number density of \( 6.4 \times 10^{-4} \, (h/\text{Mpc})^3 \) at different snapshots \( z_{\text{snap}} = 0.658, 0.725, 0.755, 0.825, 0.876, 0.950, 1.047 \) used to cover the redshift ranges \( 0.6–0.7, 0.7–0.75, 0.75–0.8, 0.8–0.85, 0.85–0.9, 0.9–1.0, 1.0–1.1 \), respectively. The fiducial cosmology of these mocks is that of the MultiDark simulation (except for \( \sigma_8 \), i.e. flat ΛCDM with

Mockes are trimmed to the tiling geometry and veto masks. We implement in the mocks the observational systematics seen in the data. The data redshift distribution is applied to the mocks in each chunk, \( z \). We introduce angular systematics by trimming mock objects according to a map built from the data observed density with a Gaussian smoothing of radius 1 deg. Contaminants, such as stars, or objects outside the redshift range \( 0.6 < z < 1.1 \) are added to the catalogues, such that the target density matches in average that of the observed data. Fibre collisions are modelled using an extension of the Guo, Zehavi & Zheng (2012) algorithm implemented in \texttt{nbodykit}, accounting for the plate overlaps and target priority. We include the TDSS (Ruan et al. 2016) targets (‘FES’ and ‘RQS1’) which were tiled at the same time as eBOSS ELGs. Finally, some objects are declared as redshift failures following their nearest neighbour in the observed data. All systematic corrections (weighting scheme and \( n(z) \) dependence in the imaging depth) are
applied the exact same way to the mocks as in the data clustering catalogues.

Fig. 7 shows the different systematics and corrections applied successively to the EZ mocks. One can already see that angular photometric systematics (photo) are the dominant ones. Another important effect is due to the shuffled scheme used to assign redshifts to randoms from the mock data redshift distribution, which leads to the aforementioned RIC, clearly visible in the quadrupole and hexadecapole at large scale.

Fig. 6 displays the power spectrum measurement of the eBOSS ELG sample (blue curve), together with the mean of the EZ mocks with veto masks only applied (baseline, orange). Accounting for the shuffled scheme in the mocks (green) resolves part of the difference between data and mocks in the quadrupole and hexadecapole on large scales. Including all systematics and corrections (red), the agreement with observed data is improved in the quadrupole.

6.3 GLAM-QPM mocks
The generation of GLAM-QPM mocks is detailed in Lin et al. (2020). The 2003 GLAM-QPM mocks are built from boxes of side 3 Gpc $h^{-1}$, with cosmology

$$h = 0.678, \quad \Omega_m = 0.307, \quad \omega_b = 0.022,$$

$$\sigma_8 = 0.828, \quad n_s = 0.96.$$  (38)

Mocks are trimmed to the tiling geometry and veto masks. Contrary to EZ mocks, we do not implement variations of the redshift distribution with imaging depth, nor imaging systematics. However, all other systematics (fibre collisions and redshift failures) are treated the same way as for EZ mocks. Again, all systematic corrections are applied the exact same way to the mocks as in the data catalogues.

7 TESTING THE ANALYSIS PIPELINE USING MOCK CATALOGUES
In this section, we first check our analysis pipeline and review how the observational systematics introduced in the approximate mocks impact BAO and RSD measurements. Although some systematic effects are difficult to model accurately in mocks, these can still be used to derive reliable estimates for part of the systematic uncertainties, a point we discuss also in this section. The other systematic uncertainties will be estimated from the data itself in Section 8.

In all tests, to fit each type of mocks, we use the covariance matrix built from the same mocks, unless otherwise stated. For reasons that will be justified in Section 8, we will use NGC and SGC (NGC + SGC) or SGC only power spectrum measurements and vary the redshift range. The baseline result will use NGC + SGC, and the redshift ranges $0.7 < z < 1.1$ and $0.6 < z < 1.1$ for the RSD and BAO fits, respectively.

7.1 Survey geometry effects
The model presented in Section 3 neglects the evolution of the cosmological background within the redshift range of the eBOSS ELG sample. To test the impact of this assumption on clustering measurements, we first fit 300 EZ periodic boxes at redshift $z_{\text{snap}} = 0.876$ (see Section 6.2), using a Gaussian covariance matrix, as in Section 5.2. We compare these measurements to those obtained on the mean of the no veto EZ mocks, that is including the (approximate) light-cone and global (tiling) footprint. In this case, we apply the corresponding window function treatment (Section 3.4) and the GIC (Section 3.5) in the model. To ease the comparison, which we present in Table 3, we extrapolate the best fits to the EZ boxes at redshift $z_{\text{snap}} = 0.876$ to the effective redshift $z_{\text{eff}} = 0.845$ of the EZ mocks, using their input cosmology of equation (37). The difference between
the extrapolated mean of the best fits to the EZ boxes and the best fit to the mean of the EZ mocks is 0.2 per cent on $f_{s\delta}$, 0.4 per cent on $D_M(z)/r_{\text{drag}}$ and 0.2 per cent on $D_M(z)/r_{\text{drag}}$, fully negligible compared to the dispersion of the mocks (12 per cent, 6 per cent, and 5 per cent, respectively, see Table 5), validating our modelling approximation of the eBOSS ELG survey as a single snapshot at redshift $z_{\text{snap}} = 0.876$ and extrapolated at $z_{\text{eff}} = 0.845$ (given their cosmology), with those from the sky-cut EZ mocks, with and without veto masks. For the EZ boxes, we quote the mean and standard deviation of the best-fitting measurements, divided by the square root of the number of realizations (300). For the sky-cut mocks, error bars are given by the dispersion of the mocks (12 per cent, 6 per cent, and 5 per cent, respectively, see Table 5), validating our treatment of the window function with the fine-grained eBOSS ELG veto masks.

The total shifts between the baseline sky-cut mocks and the EZ boxes are 0.1 per cent, 0.5 per cent, and 0.1 per cent for $f_{s\delta}$, $\alpha_s$, and $\alpha_s$. We take them as systematic shifts (under the generic denomination survey geometry).

Table 3. Comparison of the RSD measurements on EZ boxes at redshift $z_{\text{snap}} = 0.876$ and extrapolated at $z_{\text{eff}} = 0.845$ (given their cosmology), with those from the sky-cut EZ mocks, with and without veto masks. For the EZ boxes, we quote the mean and standard deviation of the best-fitting measurements, divided by the square root of the number of realizations (300). For the sky-cut mocks, error bars are given by the dispersion of the mocks.

|                      | $f_{s\delta}$ | $D_M(z)/r_{\text{drag}}$ | $D_M(z)/r_{\text{drag}}$ |
|----------------------|--------------|--------------------------|--------------------------|
| EZ boxes at $z_{\text{snap}} = 0.876$ | 0.4308$^{+0.0017}$ $^{-0.0017}$ | 18.218$^{+0.0034}$ $^{-0.0034}$ | 20.7175$^{+0.0027}$ $^{-0.0027}$ |
| EZ boxes at $z_{\text{eff}} = 0.845$ | 0.4339$^{+0.0017}$ $^{-0.0017}$ | 18.559$^{+0.0034}$ $^{-0.0034}$ | 20.1526$^{+0.0026}$ $^{-0.0026}$ |
| Mean of EZ mocks no veto ($z_{\text{eff}} = 0.845$) | 0.434$^{+0.0017}$ $^{-0.0017}$ | 18.47$^{+0.0033}$ $^{-0.0033}$ | 20.103$^{+0.028}$ $^{-0.028}$ |
| Mean of EZ mocks baseline ($z_{\text{eff}} = 0.845$) | 0.434$^{+0.0017}$ $^{-0.0017}$ | 18.47$^{+0.0033}$ $^{-0.0033}$ | 20.127$^{+0.031}$ $^{-0.030}$ |

Table 4. Different estimates of the fibre collisions fraction $f_s$. See the text for details.

|                      | NGC | SGC |
|----------------------|-----|-----|
| Tile overlap         | 0.44 | 0.35 |
| Collision fraction   | 0.47 | 0.39 |
| Simulated collision fraction | 0.46 | 0.38 |
| EZ simulated collision fraction | 0.46 ± 0.005 | 0.38 ± 0.004 |
| GLAM-QPM simulated collision fraction | 0.46 ± 0.005 | 0.39 ± 0.005 |

7.2 Fibre collisions

Fibre collisions are shown to be the dominant observational systematics in the eBOSS QSO sample (Hou et al. 2020; Neveux et al. 2020). The impact of fibre collisions can be seen on EZ mocks by comparing the green to the orange curves in Fig. 7. Here, we test their effect on cosmological fits to GLAM-QPM mocks, as these mocks are not further impacted by photometric systematics.
Table 5. Impact of systematics on RSD and RSD + BAO measurements on the GLAM-QPM and EZ mocks. We quote the median and the 16 per cent and 84 per cent percentiles as a metric of the centre and dispersion of the measurements.

We report in Table 5 the best fits to 2003 GLAM-QPM baseline mocks with only geometry and veto masks applied (baseline) and to the mocks where fibre collisions are simulated (fibre collisions). We find a systematic shift of 2.5 per cent on fσ_k (22 per cent of the dispersion of the mocks), 0.6 per cent on α_z (9 per cent), and 0.5 per cent on α_± (10 per cent).

The impact of fibre collisions can be mitigated following Hahn et al. (2017), if the fraction of collided pairs f_c and the fibre collision angular scale D_c are known. In the Hahn et al. (2017) correction, f_c = 1 corresponds to all galaxy pairs closer than the fibre collision angular scale being unobserved. Because of tile overlaps, this fraction is reduced. The fraction of collided pairs f_c can then be estimated in several ways:

(i) **Tile overlap**: The fraction of the survey area without tile overlap, estimated using the synthetic catalogue. This assumes all collisions are resolved in tile overlaps.

(ii) **Collision fraction**: The number of targets which were collided with another one (including the relevant TDSS targets), divided by the number of targets that would be assigned a fibre without tile overlap. This number is simulated with the same algorithm as that used for the EZ and GLAM-QPM mocks to implement fibre collisions, except the effect of tile overlaps (see Sections 6.2 and 6.3).

(iii) **Simulated collision fraction**: Same as collision fraction, but also simulating the number of data targets which were collided with another one (including the relevant TDSS targets), taking into account tile overlaps.
and 0 for NGC and a scatter of 1 in Fig. 8. For the redshift cut 0.7 collisions): versus baseline in the following.

developed a method to correct for such missing observations in the effective redshift of the eBOSS ELG sample distance corresponding to the fibre collision radius 62 arcsec at the 2017), is in very good agreement with the above estimates provided et al. (2017) for comparison. (2017) (left: NGC, right: SGC). See the text for details, and fig. 8 of Hahn et al. (2017), is in very good agreement with the above estimates provided 

eBOSS ELG BAO and RSD measurements 5629

(iv) EZ simulated collision fraction: Same as simulated collision fraction, in the EZ mocks. 
(v) GLAM-QPM simulated collision fraction: Same as simulated collision fraction, in the GLAM-QPM mocks.

All these estimates are calculated with veto masks applied and are reported in Table 4, using 50 mocks (for EZ and GLAM-QPM simulated collision fraction). They all agree within 2 per cent. The modelling of fibre collisions in Hahn et al. (2017) is actually based on their impact on the projected correlation function. Fig. 8 displays the ratio of the projected correlation function of the GLAM-QPM mocks with fibre collisions corrected by \( w_{\text{cor}} \) to the true one (without fibre collisions): \( f_s \), given by the height of the step function (see Hahn et al. 2017), is in very good agreement with the above estimates provided in Table 4. We therefore choose the corresponding values \( f_s = 0.46 \) for NGC and \( f_s = 0.38 \) for SGC.

For the fibre collision angular scale \( D_{\text{fc}} \), we take the comoving distance corresponding to the fibre collision radius 62 arcsec at the effective redshift of the eBOSS ELG sample \( \xi_{\text{eff}} = 0.845 \). The obtained value, 0.61 Mpc h\(^{-1}\), provides good modelling of the effect as can be seen in Fig. 8. For the redshift cut 0.7 < \( z < 1.1 \), a similar calculation provides \( D_{\text{fc}} = 0.62 \text{ Mpc h}^{-1} \).

The parameters \( f_s \) and \( D_{\text{fc}} \), being determined, the Hahn et al. (2017) correction can be included in the RSD model. Best fits to the GLAM-QPM mocks with fibre collisions are in very good agreement with the baseline mocks once the correction is included: the potential remaining systematic bias is 0.3 per cent on \( f r_s \), 0.1 per cent based on \( \alpha_r \), and 0.0 per cent on \( \alpha_s \) − 3 per cent, 2 per cent, and 0 per cent of the dispersion of the mocks, respectively (fibre collisions + Hahn et al. versus baseline in Table 5). We therefore include this correction as a baseline in the following.

Note that Bianchi & Percival (2017), Percival & Bianchi (2017) developed a method to correct for such missing observations in the \( n \)-point (configuration space) correlation function using \( n \)-tuple upweighting; for an application to the eBOSS samples (including ELG), we refer the reader to Mohammad et al. (2020). This method has been very recently extended to the Fourier space analysis by Bianchi & Verde (2019). We do not apply this technique to the eBOSS ELG sample, since most of this analysis was completed before this publication and because the effect of fibre collisions appears subdominant, especially after the Hahn et al. (2017) correction.

7.3 Radial integral constraint

As mentioned in Section 6.2, the shuffled scheme, used to assign data redshifts to randoms is responsible for a major shift of the power spectrum multipoles (purple versus red curves in Fig. 7). As discussed in de Mattia & Ruhlmann-Kleider (2019), this damping of the power spectrum multipoles on large scales is not specific to the shuffled scheme, but to any method measuring the radial selection function on the observed data itself. We report in Table 5 the cosmological measurements from RSD fits, as can be seen in the EZ mocks (orange versus blue curves in Fig. 7). These systematic bias cosmological measurements from RSD fits, as can be seen in Table 5: comparing the fits on contaminated mocks, including the fibre collision correction of Section 7.2 (all syst., fc) to uncontaminated mocks (baseline, GIC), one notices a bias of 8.8 per cent on \( fr_s \), 2.4 per cent on \( \alpha_r \), and 1.6 per cent on \( \alpha_s \) corresponding to a significant shift of respectively 75 per cent, 35 per cent, and 32 per cent of the dispersion of the best fits to the mocks.

We propose to mitigate these residual systematics by rescaling weighted randoms in HEALPix7 (Górski et al. 2005) pixels such that the density fluctuations \( F(r) \) of equation (4) are forced to 0 in each pixel (a scheme which will be referred to as the pixelated scheme in the following). This leads to an angular integral constraint (AIC), which we model and combine with the RIC following de Mattia & Ruhlmann-Kleider (2019). In Table 5, we report the RSD measurements without (baseline, GIC) and with the full angular and radial integral constraints (ARIC) modelled, applying the shuffled and pixelated schemes to the uncontaminated mock data, for two pixel sizes: \( \text{nside} = 64 (\simeq 0.84 \text{ deg}^2) \) and \( \text{nside} = 128 (\simeq 0.21 \text{ deg}^2) \). The combined radial and angular integral constraint is correctly modelled, generating only a small potential bias of 1.1 per cent on \( fr_s \), 0.5 per cent and 0.4 per cent on scaling parameters (which amounts to 10 per cent, 8 per cent, and 7 per cent of the dispersion of the mocks, respectively) for \( \text{nside} = 64 \). A similar shift is seen with \( \text{nside} = 128 \). The pixelated scheme increases statistical uncertainties by a reasonable fraction of \( \simeq 10 \) per cent.

Finally, Fig. 9 shows the best fits to the baseline (blue) and contaminated (red) EZ mocks. Measurements obtained when applying the pixelated scheme (\( \text{nside} = 64 \)) to the contaminated mocks and modelling the ARIC are shown in blue. The systematic bias quoted at the beginning of the section is clearly reduced and becomes 2.5 per cent on \( fr_s \) (21 per cent of the dispersion of the mocks), 0.4 per cent on \( \alpha_r \) (6 per cent), and 0.5 per cent on \( \alpha_s \) (12 per cent) with \( \text{nside} = 64 \), slightly less with \( \text{nside} = 128 \) (see Table 5, all syst & pix64, fc with respect to baseline, GIC).

7http://healpix.jpl.nasa.gov/
7.5 Likelihood Gaussianity

In Section 4, we assumed that we could use a Gaussian likelihood to compare data and model. While this may be accurate enough by virtue of the central limit theorem when the number of modes is high enough, it may break down on large scales where statistics is lower and mode coupling due to the survey geometry, and, in our specific case, RIC and ARIC, occurs (see e.g. Hahn et al. 2019).

Comparing the median of the fits to each individual baseline EZ mocks to the fit to the mean of the mocks (see first two rows of second series of results in Table 5, baseline, GIC versus mean of mocks baseline, GIC), we observe shifts of 2.2 per cent on $f_{\sigma 8}$ (19 per cent of the dispersion of the mocks), 1.3 per cent on $\alpha_{\parallel}$ (21 per cent), and 0.9 per cent on $\alpha_{\perp}$ (18 per cent). This bias could be due to either non-Gaussianity of the power spectrum likelihood or model non-linearity.

To test a potential bias coming from the breakdown of such a Gaussian assumption, we produce 1000 fake power spectra following a Gaussian distribution around the mean of the EZ mocks, with the covariance of the mocks, and fit them with our model (using the same covariance matrix). Results are reported in Table 5 (fake all syst. & pix64, fc). Shifts with respect to the true mocks (all syst. & pix64, fc) are 0.2 per cent on $f_{\sigma 8}$, 0.1 per cent on $\alpha_{\parallel}$, and 0.2 per cent on $\alpha_{\perp}$.

We therefore conclude that one can safely use the Gaussian likelihood to compare data and model power spectra. We also attribute the shifts between the fit to the mean of the EZ mocks and the median of the fits to each mock to model non-linearity.

7.6 Isotropic BAO

In Table 6 and hereafter, as in Ata et al. (2018), Raichoor et al. (2020), we qualify BAO detections as $\alpha$ measurements for which the best-fitting value and its error bar (determined by the $\Delta \chi^2 = 1$ level) are within the range $[0.8 \sigma_{\exp}, 1.2 \sigma_{\exp}]$ ($\alpha_{\exp}$ being the expected $\alpha$ value, given the fiducial and mock cosmologies). Statistics are provided for the $N_{\text{det}}$ mocks with BAO detections. As we include covariance matrix corrections (Hartlap factor $D$, given by equation 27) and correction to the parameter covariance matrix ($m_1$ factor, see equation A22) in the $\alpha$ measurement on each mock, we follow Percival et al. (2014) and provide the standard deviation $S$ of the $\alpha$ measurement corrected by $\sqrt{m_2}$, with $m_2$ given by equation (A32).

As stated in Section 5.5, we fix $\Sigma_0$ to 8 Mpc $h^{-1}$ (respectively 4 Mpc $h^{-1}$) when fitting pre-reconstruction (respectively post-reconstruction) power spectra. Pre-reconstruction $\alpha$ measurements on both EZ and GLAM-QPM mocks are biased slightly high, as can be seen from Table 6 (baseline pre-reconstruction versus baseline). This is in line with the expected shift of the BAO peak caused by the non-linearity of structure formation (Padmanabhan, White & Cohn 2009; Ding et al. 2018). On the contrary, post-reconstruction $\alpha$ measurements do not show any bias, at the 0.43/$\sqrt{1000}$ = 0.1 per cent level.

The RIC effect was noticed to have a significant impact on RSD cosmological measurements (Section 7.3). We find its impact to be negligible on the post-reconstruction isotropic BAO measurements (shuffled versus baseline). We thus do not model any RIC correction for the isotropic BAO fits, as it would have required an increased computation time.

Adding all observational systematics and their correction scheme (all syst.), the isotropic BAO fits to EZ mocks shift by a negligible 0.1 per cent, while no change is seen with GLAM-QPM mocks (which do not include angular photometric systematics).

As in Section 7.5, we again generate and fit (fake all syst.) 1000 fake power spectra following a Gaussian distribution with mean and covariance matrix inferred from the contaminated EZ mocks. A negligible shift of 0.1 per cent of $\alpha$ is seen with respect to the true mocks (all syst.), showing that one can safely use a Gaussian likelihood to compare data and model power spectra. A small shift of 0.1 per cent is seen between the fit to the mean of the mocks and the mean of the fits to each individual mock, which we label as model non-linearity in the following.

To support the data robustness tests presented in Section 8, we apply systematics successively to the EZ mocks. Fibre collisions lead to a negligible $\alpha$ shift of 0.1 per cent (photo + cp syst. versus photo syst.).

Redshift failures do not impact the $\alpha$ measurement (all syst. versus photo + cp syst.). Ignoring the correction weight $w_{\text{noz}}$ and removing redshift failures from the mocks used to build the covariance matrix is equally harmless (all syst. no $w_{\text{noz}}$ versus all syst.). A negligible shift is seen as well when the correction weight $w_{\text{noz}}$ is not used, and redshift failures are removed from the mocks used to build the covariance matrix (all syst. rand noz & pix64, fc, no $w_{\text{noz}}$). Note, however, that the modelling of redshift failures in the mocks is complex since we have no perfect knowledge of the corresponding systematics in the observed data. In the above, redshift failures are implemented in the EZ mocks following a deterministic process: a mock object is declared a redshift failure if the redshift of its nearest neighbour in the data could not be reliably measured. Such a scheme overestimates the angular impact of redshift failures. We therefore produce and analyse a second set of mocks, where redshift failures are applied to the EZ mocks with a probability following the model fitted on the data catalogue. In this case (rand noz), shifts in the measured $\alpha$ due to redshift failures are equally small.

The recovered $\alpha$ does not change when k-bin centres are shifted by half a bin ($0.005 \text{ Mpc}^{-1}$, all syst. + 1/2 k-bin). Fitting the EZ mocks with the covariance matrix estimated from GLAM-QPM mocks results in a small 0.1 per cent shift of $\alpha$ measurements. The same behaviour is seen when using the covariance matrix from EZ mocks without systematics (with the shuffled scheme only, no syst. cov).
Isotropic BAO measurements on EZ and GLAM-QPM OuterRim mocks in different conditions. We quote statistics for the $N_{\text{sim}}$ mocks with BAO detection, i.e. mocks for which $\alpha - \sigma_{\text{low}} > 0.8\,\sigma_{\text{exp}}$ and $\alpha + \sigma_{\text{up}} < 1.2\,\sigma_{\text{exp}}$. ($\alpha$) is the mean $\alpha$, $\langle \sigma \rangle$ the mean $\Delta \chi^2 = 1$ error ($=\langle \sigma_{\text{low}} + \sigma_{\text{up}} \rangle/2$). $S$ is the standard deviation of $\alpha$, rescaled by $\sqrt{m_2}$, with $m_2$ given by equation (A32) (the uncorrected value is provided in brackets). Expected values $\alpha_{\text{exp}}$ are given at the top of each sub-table (in the $\langle \alpha \rangle$ column).

Based on the previous tests, we determine two systematic effects to be included in the final systematic budget: the model non-linearity, since it can only be measured on mocks, and fibre collisions, as we believe our modelling of the effect in the EZ mocks (see Section 6.2) to be quite representative of the actual data fibre collisions. We directly take the shift in $\alpha$ attributed to model non-linearity as a systematic bias. The 0.1 per cent $\alpha$ shift attributed to fibre collisions is below twice the mock-to-mock dispersion divided by the square root of the number of mocks (common detections), i.e. $2 \times 3.8$ per cent/$\sqrt{962} \simeq 0.2$ per cent, a value which we take as a systematic uncertainty, following the same procedure as in Neveux et al. (2020), Gil-Marín et al. (2020).

One would notice that the mean error on $\alpha$ measurements on EZ and GLAM-QPM mocks (defined by the $\Delta \chi^2 = 1$ level, see Section 4.3) is systematically and significantly lower than the dispersion of the best-fitting values. The value of the damping parameter $\Sigma_{\text{gal}} = 4 \, \text{Mpc} \cdot \text{h}^{-1}$ is chosen to match the BAO amplitude seen in the reconstructed OuterRim mocks (see Section 5.5). However, the BAO amplitude is significantly less pronounced in the EZ mocks (see e.g. Raichoor et al. 2020), hence favouring a larger $\Sigma_{\text{gal}} = 6 \, \text{Mpc} \cdot \text{h}^{-1}$. When this value is used, the distribution of the residuals $(\alpha - \langle \alpha \rangle)/\langle \sigma \rangle$ of mocks with BAO detection is consistent with a standard normal distribution, as shown by the Kolmogorov–Smirnov test of Fig. 10. Using a lower $\Sigma_{\text{gal}}$ artificially decreases the error on the BAO fits to EZ or GLAM-QPM mocks. Since we determined $\Sigma_{\text{gal}}$ on the more accurate OuterRim-based mocks, we conclude that statistical errors quoted on the data measurement are fairly estimated.

---

**Table 6.** Isotropic BAO measurements on EZ and GLAM-QPM OuterRim mocks in different conditions. We quote statistics for the $N_{\text{sim}}$ mocks with BAO detection, i.e. mocks for which $\alpha - \sigma_{\text{low}} > 0.8\,\sigma_{\text{exp}}$ and $\alpha + \sigma_{\text{up}} < 1.2\,\sigma_{\text{exp}}$. ($\alpha$) is the mean $\alpha$, $\langle \sigma \rangle$ the mean $\Delta \chi^2 = 1$ error ($=\langle \sigma_{\text{low}} + \sigma_{\text{up}} \rangle/2$). $S$ is the standard deviation of $\alpha$, rescaled by $\sqrt{m_2}$, with $m_2$ given by equation (A32) (the uncorrected value is provided in brackets). Expected values $\alpha_{\text{exp}}$ are given at the top of each sub-table (in the $\langle \alpha \rangle$ column).

---

**Figure 10.** Kolmogorov–Smirnov test on the residuals of EZ mocks, with $\Sigma_{\text{gal}} = 6 \, \text{Mpc} \cdot \text{h}^{-1}$, for the BAO fits.

**7.7 Combination of RSD and BAO measurements**

As already mentioned in Section 4, we combine the RSD and BAO likelihoods, taking into account the cross-covariance between pre- and post-reconstruction power spectrum measurements.

In Table 5, one can notice a small shift between the RSD and the RSD + BAO fit to the mean of the baseline EZ mocks: 1.0 per cent on $f_{\alpha_1}$, 0.3 per cent on $\alpha_{\text{obs}}$, and 0.5 per cent on $\alpha_{\text{obs}}$, which we quote as systematic error related to the technique of combining RSD and BAO likelihoods. These shifts may come from residual systematic differences between BAO template and mocks which contaminate the RSD part of the likelihood through its cross-covariance with the BAO part. We do not investigate this effect further since these
biases remain small (< 10 per cent) compared to the dispersion of the mocks (and thus to the data measurement errors).

Again, RSD + BAO measurements on contaminated (all syst., fc) mocks are strongly biased: 9.2 per cent on $f_{\sigma 8}$ (86 per cent of the dispersion of the mocks), 2.1 per cent on $\alpha_\parallel$ (41 per cent), and 1.6 per cent on $\alpha_\perp$ (42 per cent). When applying the pixelated scheme (nside = 64), one recovers reasonable systematic shifts with respect to (baseline, GIC) of 2.5 per cent on $f_{\sigma 8}$, 0.6 per cent on $\alpha_\parallel$, and 0.5 per cent on $\alpha_\perp$. These shifts reduce further when using nside = 128, but we choose the pixelated scheme with nside = 64 as it induces a bias which we estimate small enough for our analysis since it represents 24 per cent of the dispersion of the mocks on $f_{\sigma 8}$, 11 per cent on $\alpha_\parallel$, and 13 per cent on $\alpha_\perp$. In addition, the pixelated scheme (which involves integrating over all scales of the model correlation function) has only been tested up to nside = 64 with $N$-body based mocks in de Mattia & Ruhlmann-Kleider (2019). Moreover, the data clustering measurement is also plagued by the complex dependence of $n(z)$ with imaging quality, which we only partly removed through the $\sin \theta \sin \phi \Delta z$ splitting of the radial selection function in Section 6.1. This will require estimating the potential residual systematics from the data itself (see Section 8.2), which will prove to be large so that the previously mentioned shifts become subdominant.

We note the potential systematic bias induced by applying the radial and angular integral constraints (shuffled & pix64, ARIC versus baseline, GIC): 0.8 per cent on $f_{\sigma 8}$, 0.6 per cent on $\alpha_\parallel$, and 0.1 per cent on $\alpha_\perp$. These shifts are more than twice the mock-to-mock dispersion, divided by the square root of the number of mocks (0.4 per cent on $f_{\sigma 8}$, 0.1 per cent on $\alpha_\parallel$, and 0.1 per cent on $\alpha_\perp$). We therefore account for the ARIC modelling in our systematic budget by taking an error of 0.8 per cent on $f_{\sigma 8}$, 0.6 per cent on $\alpha_\parallel$, and 0.1 per cent on $\alpha_\perp$.

The isotropic BAO template of equation (24) contains a bias term $B_{\text{nu}}$, which we so far forced to be equal to the linear bias $b_1$ of the RSD model (see equation 13). We try to let it free ($B_{\text{nu}}$ free) and see no shift on cosmological parameters. We thus keep $B_{\text{nu}} = b_1$ in the following.

As in Section 7.5, we generate and fit (fake all syst.) 1000 fake power spectra following a Gaussian distribution with mean and covariance matrix inferred from the contaminated EZ mocks. Negligible shifts of 0.3 per cent on $f_{\sigma 8}$, 0.1 per cent on $\alpha_\parallel$, and 0.1 per cent on $\alpha_\perp$ are seen with respect to the true mocks (all syst. & pix64, fc), showing that using a Gaussian likelihood to compare data and model power spectra is accurate enough. However, we find small systematic shifts of 1.6 per cent on $f_{\sigma 8}$ (15 per cent of the dispersion of the mocks), 1.0 per cent on $\alpha_\parallel$ (17 per cent), and 0.4 per cent on $\alpha_\perp$ (11 per cent) between the median of the best fits to each individual mock and the fit to the mean of the mocks (baseline, GIC versus mean of mocks baseline, GIC). As in Section 7.5, we attribute this bias to the model non-linearity, which one would note is slightly reduced compared to the RSD only analysis.

We check that the error bars measured on each individual mock (defined by the $\Delta X^2 = 1$ level, see Section 4.3) are correctly estimated by performing a similar test as done on the post-reconstruction isotropic BAO fits in Section 7.6. For this Kolmogorov–Smirnov test shown in Fig. 11, we use $\Sigma_{\text{al}} = 6 \text{Mpc} h^{-1}$, and keep only mocks for which the best-fitting $\alpha_\parallel$ and $\alpha_\perp$ and their error bars (divided by the $\alpha_\parallel$ and $\alpha_\perp$ expected values) are within the range $[0.8, 1.2]$. The residuals seem to be in correct agreement with a standard normal distribution, as expected. We checked that the $f_{\sigma 8}$ residuals remain very compatible with a standard normal distribution when considering all mocks (i.e. without cut on $\alpha_\parallel$ and $\alpha_\perp$ best fits and error bars).

7.8 Further tests

In Section 8, we will justify our choice to fit the data with the redshift cut $0.7 < z < 1.1$. The expected shift on $f_{\sigma 8}$ due to the change in effective redshift is 0.3 per cent. As can be seen in Table 5 (all syst. pix64, fc), the effect of this redshift cut on the EZ mocks is negligible.

As in Section 7.6, to support the data robustness tests presented in Section 8, we apply systematics successively to the EZ mocks.

Fibre collisions shift $f_{\sigma 8}$, $\alpha_\parallel$, and $\alpha_\perp$ by 1.1 per cent, 0.6 per cent, and 0.0 per cent, respectively ($\sigma + \text{cp syst.} \ & \ \text{pix64}, \ \text{fc}$ versus $\text{photo syst.} \ & \ \text{pix64}$). The $\alpha_\perp$ shift lies below twice the mock-to-mock dispersion divided by the square root of the number of mocks, 0.2 per cent, which we therefore take as a systematic uncertainty for this parameter. This is not the case for $f_{\sigma 8}$ (0.5 per cent) and $\alpha_\parallel$ (0.2 per cent), for which we take the measured shifts 1.1 per cent, 0.6 per cent as systematic uncertainty, following the same procedure as in e.g. Neveux et al. (2020). In Section 7.2, our several estimates of the $f_i$ parameter required for the Hahn et al. (2017) fibre collision correction differed by 2 per cent at most. To assess the impact of this additional uncertainty, we compare best fits with and without the Hahn et al. (2017) fibre collision correction: we find shifts on $f_{\sigma 8}$, $\alpha_\parallel$, and $\alpha_\perp$ of 1.3 per cent, 0.1 per cent, and 0.5 per cent, respectively. Multiplying these variations by the uncertainty of 2 per cent leads to a very small additional uncertainty, which we thus neglect.

Despite the weights $w_{\text{sys,l}}$ and the pixelated scheme, redshift failures (red versus green curves in Fig. 7) produce shifts of 2.3 per cent, 0.5 per cent, and 0.5 per cent on $f_{\sigma 8}$, $\alpha_\parallel$, and $\alpha_\perp$ (all syst. & pix64, fc versus $\sigma$)$+$photo syst. & pix64, fc). These shifts become 2.6 per cent, 0.9 per cent, and 0.4 per cent on $f_{\sigma 8}$, $\alpha_\parallel$, and $\alpha_\perp$ when the correction weight $w_{\text{sys,l}}$ is not used, and redshift failures are removed from the mocks used to build the covariance matrix (all syst. & pix64, fc, no $w_{\text{sys}}$). A much smaller systematic shift is seen with respect to angular photometric systematics and fibre collisions only ($\sigma + \text{cp syst.} \ & \ \text{pix64}, \ \text{fc}$) for EZ mocks with the stochastic implementation of redshift failures (all syst. rand noz & pix64, fc): 0.1 per cent on $f_{\sigma 8}$, 0.4 per cent on $\alpha_\parallel$, and 0.1 per cent on $\alpha_\perp$.

We finally test the robustness of our analysis when using a covariance matrix measured from the GLAM-QPM mocks (without angular photometric systematics), from EZ mocks without systematics (no syst. cov), and when shifting the k-bin centres by half a bin (0.005 $h$ Mpc$^{-1}$, all syst. + 1/2 k-bin). In all these cases, best fits to the EZ mocks remain stable.

We therefore conclude that our analysis pipeline is robust enough to perform the BAO and RSD + BAO measurements on the eBOSS ELG data. Based on the previous tests, four systematic effects estimated on mocks (survey geometry, model non-linearity, ARIC modelling, fibre collisions) will be included in the final systematic budgets presented in the next section.

8 RESULTS

In this section, we present isotropic BAO, RSD, and combined RSD + BAO measurements on the eBOSS DR16 ELG data, discuss robustness tests of those results and provide the final error budget, including statistical and systematic contributions. In particular, systematic uncertainties are estimated from data itself where we consider mocks cannot give a reliable estimate.
8.1 Isotropic BAO measurements

As decided in Section 5.5, we take $\Sigma_{nl} = 4 \text{ Mpc}^{-1}$ as fiducial value for the BAO damping and BAO templates are computed within the fiducial cosmology (10), except otherwise stated. Fig. 12 shows the BAO oscillation pattern fitted to the observed ELG NGC + SGC data. One would note that NGC does not show a clear BAO feature, contrary to SGC. The best-fitting $\alpha$ and its $\sigma$ error are provided for both SGC and NGC + SGC fits in Table 7. For both fits, $\alpha \pm \sigma$ lies well in $[0.8, 1.2]$\footnote{Here, we assume that fiducial cosmology (10) agrees with the true one such that the BAO peak positions differ by much less than 20 per cent.}, the criterion used in Section 7.6 to qualify detections in the mocks. However, in the NGC alone, the best-fitting $\alpha$ value is 0.79, such that the aforementioned criterion is not met. The same test, using the same BAO template in fiducial $\alpha = 0.98^\pm 0.04$ for the SGC and $\alpha = 0.95^\pm 0.09$ for the NGC, to match their BAO signal amplitude and to sky-cut OuterRim mocks of Section 5.5 (with $\Sigma_{nl} = 2.4 \text{ Mpc}^{-1}$, to match their BAO signal amplitude), as reported in Table 8 ($\alpha \pm \sigma \notin [0.8, 1.2]$ line). Sky-cut OuterRim mocks (hereafter OR mocks), based on N-body simulations, provide the expected BAO detections in the absence of non-Gaussian contributions due to systematics.\footnote{We note however that in the OuterRim cosmology (34) the BAO amplitude (and hence signal to noise of BAO fits) is slightly larger than the Planck Collaboration VI (2018) best-fitting model.} In contrast, EZ mocks include known data systematics, but their BAO amplitude is lower than expected given their cosmology. Altogether, we expect the correct BAO detection rate to lie between values derived from EZ mocks and OR mocks. One notices that 9 per cent of the EZ mocks and 2.5 per cent of the OR mocks fail to match the $\alpha \pm \sigma$ criterion in both the NGC and SGC. Therefore, the probability that $\alpha$ does not lie in $[0.8, 1.2]$ within errors, for either the NGC or the SGC, ranges from 5 per cent (OR mocks) to 17 per cent (EZ mocks), such that, with this criterion, the behaviour of the data is not very unexpected. This is in line with conclusions drawn in the configuration space BAO analysis (Raichoor et al. 2020).

To further quantify the BAO signal we compute the $\chi^2$ difference between the best fits obtained with the wiggle and no-wiggle power spectrum templates (see Section 3.6). The $\chi^2$ profiles using the wiggle and no-wiggle power spectrum templates are shown in Fig. 13. Combining NGC and SGC we find $\Delta \chi^2 = -1.95$ (1.4$\sigma$) at a best-fitting value denoted $\alpha_{\text{NSGC}}$ in the following. Note however that the best-fitting $\alpha$ value may not be relevant to compute the $\Delta \chi^2$ criterion when too far from the true one if the data (or mock) vector is too noisy. Therefore, for data or mock fits performed on each cap (NGC and SGC) separately, we quote in Table 8 the $\Delta \chi^2$ value evaluated at
The BAO signal is noticeable in eBOSS SGC post-reconstruction data, not Data versus mock BAO

difference \( \Delta \chi^2 \) between the wiggle and no-wiggle template best fits for data and mocks is provided at the

with all systematics implemented and for OuterRim mocks (using \( \Sigma_{\text{all}} = 2.4 \text{ Mpc} h^{-1} \)). The \( \chi^2 

\) difference \( \Delta \chi^2 \) between the wiggle and no-wiggle template best fits for data and mocks is provided at the

which show a larger \( \Delta \chi^2 \) than the data (and hence weaker BAO detection) at \( \alpha = \alpha_{\text{NSGC}} \) and \( \alpha = \alpha_{\text{exp}} \), respectively.

\[ \begin{array}{c|c|c|c}
\text{NGC} & \text{SGC} & \text{NGC + SGC} \\
\hline
\Delta \chi^2(\alpha = \alpha_{\text{NSGC}}) & 3.58 & -5.53 & -1.95 \\
\Delta \chi^2(\alpha = \alpha_{\text{exp}}) & 3.97 & -5.61 & -1.63 \\
\text{all syst. EZ mocks} & & & \\
\hline
N(\alpha \pm \sigma \not\in [0.8, 1.2]) & 91 & 90 & 26 \\
N(> \Delta \chi^2(\alpha = \alpha_{\text{NSGC}})) & 18 & 846 & 184 \\
N(> \Delta \chi^2(\alpha = \alpha_{\text{exp}})) & -2.62 & -1.92 & -4.54 \\
N(> \Delta \chi^2(\alpha = \alpha_{\text{exp}})) & 21 & 881 & 269 \\
\hline
\text{Sky-cut OuterRim mocks} & & & \\
\hline
N(\alpha \pm \sigma \not\in [0.8, 1.2]) & 25 & 23 & 6 \\
N(\alpha = \alpha_{\text{NSGC}}) & -5.38 & -4.48 & -9.85 \\
N(> \Delta \chi^2(\alpha = \alpha_{\text{NSGC}})) & 6 & 601 & 68 \\
N(> \Delta \chi^2(\alpha = \alpha_{\text{exp}})) & -7.42 & -4.07 & -8.79 \\
N(> \Delta \chi^2(\alpha = \alpha_{\text{exp}})) & 17 & 654 & 102 \\
\end{array} \]

the corresponding NGC + SGC best-fitting value rather than at the respective NGC or SGC best fits, which are more subjective to noise. We also provide the \( \Delta \chi^2 \) taken at the expected \( \alpha \) value, given our fiducial cosmology, \( \alpha_{\text{exp}} = 1 \) for all data. We find that for NGC + SGC, the mean \( \Delta \chi^2(\alpha = \alpha_{\text{NSGC}}) \) is lower in the mocks, meaning a better BAO detection. However, 18 per cent EZ mocks and 7 per cent OR mocks have larger \( \Delta \chi^2 \) values, i.e. worse BAO detection, than the data (see \( N(> \Delta \chi^2(\alpha = \alpha_{\text{NSGC}})) \) line in Table 8). So according to this criterion, the behaviour of the data is not very unexpected. A similar conclusion holds when taking \( \Delta \chi^2 \) at \( \alpha = \alpha_{\text{exp}} \) (see \( N(> \Delta \chi^2(\alpha = \alpha_{\text{exp}})) \) in Table 8). Focusing on the SGC, \( \Delta \chi^2(\alpha = \alpha_{\text{NSGC}}) \) is smaller (better BAO detection) in data than in 85 per cent of the EZ mocks and 60 per cent of the OR mocks. However, only 1.8 per cent of EZ mocks and 0.6 per cent of OR mocks show a larger \( \Delta \chi^2(\alpha = \alpha_{\text{NSGC}}) \) (worse BAO detection) than the NGC data. Therefore, the probability for such a poor BAO detection to happen in either NGC or SGC is approximately twice higher, of the order of a few per cents. Again similar conclusions hold when taking \( \Delta \chi^2 \) at \( \alpha = \alpha_{\text{exp}} \). We emphasize however that the above figures are tied to the statistics used to qualify the BAO detection.

We have seen that contrary to SGC the poor BAO detection in the NGC is statistically unlikely (even given the known observational systematics implemented in the EZ mocks). Let us now discuss whether one can combine the two caps. We note that NGC photometry is shallower than SGC and thus more prone to (potentially unknown) photometric systematics (Raichoor et al. 2020). SGC only and combined NGC + SGC fits are similar, to the 1.1 per cent level (0.6 < \( z < 1.1 \) in Table 7), which is statistically expected, as seen in 75/1000 EZ mocks (considering both tails). Hence, there is no hint of a strong, unexpected systematic shift in the combined fit, due the addition of potentially contaminated NGC data. We also note that this 1.1 per cent shift is smaller than 1.3 per cent, the uncertainty related to photometric systematics included in our systematic budget (see Table 9), and hence is already accounted for if the NGC was the major source of photometric systematics. As a conclusion, we do not see any reason to reject NGC data in the fit. Moreover, combining NGC + SGC turns out to be more optimal than considering SGC alone, even given the poor BAO detection in NGC. To check this, we select EZ mocks with \( \Delta \chi^2(\alpha = \alpha_{\text{NSGC}}) > 0 \) in the NGC but \( \Delta \chi^2(\alpha = \alpha_{\text{NSGC}}) < 0 \) in the SGC among mocks for which the NGC + SGC combination fulfills \( \alpha \pm \sigma \in [0.8, 1.2] \). The dispersion of \( \alpha \) measurements in the obtained sample of 130 mocks is 0.048 for NGC + SGC, less than 0.058 for SGC alone. In addition, a Kolmogorov–Smirnov test (similar to that of Fig. 10) does not show any misestimation of error bars (\( p \)-value of 0.533 for the residuals to be consistent with a standard normal distribution). A similar reduction of error bars is seen in data in Table 7 (\( ^{+0.025}_{-0.028} \) versus \( ^{+0.032}_{-0.034} \)). Hence, we find it legitimate to combine NGC and SGC measurements.

To further check that error bars are still correctly estimated in the low signal-to-noise regime, we select NGC + SGC EZ mocks for which \( \Delta \chi^2(\alpha = \alpha_{\text{NSGC}}) \) is larger than that observed in the data

\[ \Delta \chi^2(\alpha = \alpha_{\text{exp}}) \]
(while still restricting to $\alpha \pm \sigma \in [0.8, 1.2]$). Again, in this sample of 165 EZ mocks, a Kolmogorov–Smirnov test shows no hint for a misestimation of error bars (the $p$-value for the residuals to be consistent with a standard normal distribution is 0.459). Therefore, the method to estimate statistical uncertainties in data appears to be correct. We note however that data statistical error bars ($+0.025$; see Table 7) are smaller than those seen in mocks on average ($\sigma \approx 0.033$, see Table 6); 246/1000 EZ mocks have smaller statistical error bars than data (using $\Sigma_{\text{nl}} = 4 \text{ Mpc} h^{-1}$ for both data and mocks). In a sample of EZ mocks for which $\Delta x^2(\alpha = \alpha_{\text{NGC}})$ is within $\pm 1$ of the data $\Delta x^2(\alpha = \alpha_{\text{NGC}})$, which may be considered as representative of the data affinity for BAO, we find 6/157EZ mocks to have smaller statistical error bars than the data.11 Due to the low average BAO amplitude in the EZ mocks and the additional residual systematics in the data, this fraction slightly underestimates the probability to obtain smaller error bars than in data. Altogether, though small, data statistical error bars are not too unlikely.

We now turn to stability tests performed on data. Beforehand, we emphasize that despite the low significance of the BAO signal, a robust measurement of the BAO position is possible because the relative amplitude of oscillations is imposed as a prior in the BAO model (Section 3.6). In other words, though a model without BAO is not disfavored by the data, a model with BAO far from the maximum of the likelihood is a significantly worse fit to the data.

In Raichoor et al. (2020, fig. 10), variations of the redshift density with photometric depth were noted to be relatively higher in the low-redshift end, $0.6 < z < 0.7$. We therefore test the robustness of our measurement with the lower $z$-limit. Best fits do not move significantly with the lower $z$ cut (given the change in the sample statistics), as can also be seen in Fig. 13. For example, between $0.6 < z < 1.1$ and $0.7 < z < 1.1$ the best-fitting $\alpha$ moves by 0.4 per cent. This is not significant as a larger shifts happen in 378/1000 (considering both tails: 741/1000) EZ mocks. We thus use the full redshift range $0.6 < z < 1.1$ for our isotropic BAO measurement.

The $\alpha$ measurement remains very stable with the assumed $\Sigma_{\text{nl}}$ value in SGC only. For NGC + SGC, some 0.8 per cent shift (27 per cent of the statistical uncertainty) is obtained between $\Sigma_{\text{nl}} = 4 \text{ Mpc} h^{-1}$ and $\Sigma_{\text{nl}} = 6 \text{ Mpc} h^{-1}$. A larger shift happens for 97/1000 (considering both tails: 214/1000) EZ mocks. To account for the uncertainty in the expected amplitude of the BAO signal, we include this shift as an additional uncertainty.

We estimate the potential residual systematics due to the imperfect modelling of the variations of the survey selection function with imaging quality (see Section 6.1) by comparing the measurement obtained with the baseline correction to that without any mitigation. Namely, random redshifts are taken separately in each chunk (instead of chunk-z) to measure the data power spectrum. The covariance matrix is built from mocks where we do not introduce photometric systematics nor variations of the redshift density with chunk-z. We take care to change the model window functions (see Section 3) accordingly. A shift in $\alpha$ of 1.3 per cent, which we take as systematic uncertainty, is noticed between these two configurations. One would notice that a variation of 0.6 per cent is seen in the SGC alone. Hence, the shift of the NGC + SGC best fit appears to be mainly driven by the NGC, as can be expected since photometry is shallower in the NGC than in the SGC.

The residual systematics remaining after the redshift failure correction (see Section 6.1) are similarly estimated by comparing the measurement obtained with the baseline correction to that without any mitigation ($\text{no} \ w_{\text{NL}}$). Namely, no $w_{\text{NL}}$ are applied to measure the data power spectrum, while we do not introduce redshift failures in the mocks to construct the covariance matrix. This leads to a shift in $\alpha$ of 0.2 per cent; a larger variation is seen in 438/1000 (considering both tails: 851/1000) EZ mocks, making it quite likely. Note however that data and EZ mock shifts are expected to match since a mock object is deterministically declared a redshift failure if the redshift of its nearest neighbour in the data could not be reliably measured. As mentioned in Section 7.8, a second set of mocks was produced with redshift failures being randomly drawn from the model fitted to the data; in this case, we find a larger variation in 378/1000 (considering both tails: 826/1000) EZ mocks. Hence, the shift seen in the data is well explained by the mocks. We conservatively include it in the systematic budget to account for the uncertainty in the redshift failure correction.

Changing the covariance matrix for that based on GLAM-QPM mocks, which does not include angular nor radial photometric systematics leads to a small $\alpha$ shift of 0.4 per cent in the no chunk-z case (no chunk-z G-Q cov versus no chunk-z). Similarly, in the baseline case, using a covariance matrix built from GLAM-QPM or EZ mocks without systematics (only the shuffled scheme) induces small shifts of 0.2 per cent (GLAM-QPM cov versus baseline). A larger shift is observed in the former case for 283/1000 (considering both tails: 732/1000) EZ mocks, in the latter case for 377/1000 (considering both tails: 713/1000) EZ mocks. The parameter covariance matrix correction equation (A22) already leads to an increase of 0.7 per cent of the statistical error, which is higher than obtained by summing the shifts above in quadrature (0.3 per cent). We therefore do not include any systematic uncertainty related to the choice of the covariance matrix. Dividing the number of mocks used to build the covariance matrix by 2, we find a shift in $\alpha$ of 0.5 per cent (500 mocks in cov versus baseline). This would lead to a 1.9 per cent increase of the error if added in quadrature, while the increase of error bars required to account for the change in covariance matrix between these two configurations is 1.5 per cent. Hence, the shift seen in the fit is compatible with a statistical fluctuation and we conclude that the estimation of the covariance matrix is robust enough for this measurement.

Moving the centre of the $k$-bin by half a bin (0.005 h Mpc$^{-1}$, $+1/2$-bin) leads to a $\alpha$ shift of 0.5 per cent, which is compatible with a statistical fluctuation since a larger shift is observed for 307/1000 (considering both tails: 595/1000) EZ mocks. We therefore do not include any additional uncertainty related to the choice of $k$-bins in our systematic budget.

Finally, we change the fiducial cosmology equation (10) for the OuterRim cosmology equation (34), and for comparison purposes we report the $\alpha$ value rescaled to our fiducial cosmology. Some shift can be seen (OR cosmo versus baseline), which we relate to the change of damping term. Indeed, we checked that analysing a power spectrum in our fiducial cosmology with an OuterRim template leads to a preferred $\Sigma_{\text{nl}} \approx 5.4 \text{ Mpc} h^{-1}$. The measurement obtained with $\Sigma_{\text{nl}} = 6 \text{ Mpc} h^{-1}$ and OuterRim cosmology (OR cosmo $\Sigma_{\text{nl}} = 6 \text{ Mpc} h^{-1}$) is indeed close (within 0.2 per cent) to the measurement using $\Sigma_{\text{nl}} = 4 \text{ Mpc} h^{-1}$ and our fiducial cosmology $[0.6 < z < 1.1$ (fiducial)]. This shift can be seen in 428/1000 (considering both tails: 840/1000) EZ mocks and is within the 0.2 per cent modelling uncertainty derived in Section 5.5. We therefore do not include any additional uncertainty due to the assumed fiducial cosmology.

Overall, despite the mild preference for BAO in the eBOSS ELG sample, the BAO measurement appears relatively robust. The

\footnote{This fraction increases to 39/157 when comparing data total error bars (including systematics, see Table 9) to mock statistical error bars.}
final error budget is reported in Table 9. Since the 0.1 per cent $\alpha$ shift attributed to model non-linearity is closer to a bias than a systematic uncertainty, we decided to be conservative and to add it linearly to the statistical uncertainty. All other contributions to the systematic budget are uncertainties due to the model accuracy (modelling systematics) or our limited knowledge of the survey selection function (photometric systematics, fibre collisions, redshift failures) or are analysis choices (damping term). We thus add them in quadrature to the statistical uncertainty.

Our final post-reconstruction isotropic BAO measurement is $\alpha = 0.986^{+0.031}_{-0.033}$, including statistical and systematic uncertainties.

In terms of the volume-averaged distance $D_V(z)$, we find

$$D_V(z_{eff}) = 0.845/D_{dag} = 18.33^{+0.57}_{-0.62},$$

(39)

independently of the assumed fiducial cosmology.

In order to generate the BAO likelihood profile for further cosmological inference, we first rescale $\Delta\chi^2(x;\alpha) = \chi^2(x;\alpha) - \chi^2(\alpha_0)$ (with $\alpha_0$ the best-fitting value) by the inverse of the parameter covariance rescaling (A22). To include the systematic error budget we further rescale $\Delta\chi^2(x)$ by the ratio $(\sigma_{\alpha,stat}/\sigma_{\alpha,0,stat})^2$, with $\sigma_{\alpha,0,stat}$ the total and statistical upper (lower) error bars when $\alpha > \alpha_0$ ($\alpha < \alpha_0$). We finally provide the BAO likelihood $e^{-\Delta\chi^2(DV/r_{dag})/2}$, with $D_V = \alpha D_{V0}^{66}$.

8.2 Combined RSD and BAO measurements

RSD and combined RSD + BAO measurements are reported under different fitting conditions in Table 10. As in Section 8.1, we take $\Sigma_{\alpha} = 4 \text{ Mpc}^{-1}$ as fiducial value for the BAO damping and RSD and BAO templates are computed within the fiducial cosmology (10), except otherwise stated. We quote results for the combined caps NGC + SGC and SGC alone.

As already noted in Section 8.1, variations of the redshift density with photometric depth were observed to be relatively higher in the low-redshift end. We therefore test the robustness of our measurement with respect to the lower redshift cut. For the RSD + BAO measurement, shifts of 6.4 per cent, 4.1 per cent, and 0.4 per cent are seen for $f_{rs}$, $\alpha_+$, and $\alpha_-$, respectively, when changing the redshift range $0.6 < z < 1.1$ to $0.7 < z < 1.1$ for the pre-reconstruction power spectrum (RSD part of the likelihood). Larger shifts are observed for $f_{rs}$, $\alpha_+$, and $\alpha_-$, respectively, for the baseline correction weight ($w_{\text{cor}}$). We measure shifts of 6.1 per cent on $f_{rs}$, 0.3 per cent on $\alpha_+$, and 0.3 per cent on $\alpha_-$, which we take as systematic uncertainty.

Larger variations happen for $176/1000$ (considering both tails: $368/1000$, $479/1000$ ($856/1000$), and $409/1000$ ($882/1000$) EZ mocks, respectively. If we rather consider EZ mocks where redshift failures are stochastic, based on the model fitted to the observed data, we find larger shifts for $146/1000$ (considering both tails: $318/1000$, $499/1000$ ($880/1000$), and $403/1000$ ($862/1000$) EZ mocks for $f_{rs}$, $\alpha_+$, and $\alpha_-$, respectively.

Dividing the number of mocks used to build the covariance matrix by 2, we find a shift of 4.3 per cent on $f_{rs}$, 0.1 per cent on $\alpha_+$, and 0.0 per cent on $\alpha_-$ ($500 \text{ mocks in cov versus baseline}$). This would lead to a 1.7 per cent, 0.0 per cent, and 0.0 per cent increase of the error if added in quadrature, less than 5.8 per cent, the typical increase of error bars required to account for the change in covariance matrix between these two configurations. We thus conclude that the RSD + BAO covariance matrix is stable with respect to the number of mocks.

Changing the covariance matrix built from contaminated EZ mocks for the one obtained from GLAM-QPM mocks, we find a 5.6 per cent shift on $f_{rs}$, 1.5 per cent on $\alpha_+$, and 1.6 per cent on $\alpha_-$. Larger variations happen for $171/1000$, $218/1000$, $107/1000$ EZ mocks, respectively (considering both tails: $363/1000$, $402/1000$, and $290/1000$). Even larger shifts are seen when using a covariance matrix based on EZ mocks without systematics (only the shuffled scheme, no syst. cov): 12.9 per cent shift on $f_{rs}$, 4.7 per cent on $\alpha_+$, and 1.2 per cent on $\alpha_-$. These changes happen for $12/1000$, $18/1000$, $252/1000$ EZ mocks, respectively (considering both tails: $27/1000$, $50/1000$, and $428/1000$).

One would also notice a large change (26.7 per cent on $f_{rs}$, 5.4 per cent on $\alpha_+$, and 4.7 per cent on $\alpha_-$) for the SGC only.
Table 10. RSD and RSD + BAO best fits on the eBOSS DR16 ELG sample. Error bars are defined by the $\Delta \chi^2 = 1$ level, except in the Bayesian case, where we consider the minimum interval which contains 68 per cent of the MCMC samples.

Measurements with the GLAM-QPM covariance matrix (GLAM-QPM cov). A larger shift in \(f_{sg}\) happens for 4/1000 EZ mocks (considering both tails: 18/1000). One may be concerned by some possible coupling between the data and the covariance matrix from contaminated EZ mocks, as the map of angular systematics injected in these mocks was inferred directly from the smoothed observed data density (see Section 6.2). In Appendix C, we show that we cannot find any evidence for this coupling based on EZ mocks.
The variations in the best-fitting parameters with the covariance matrix being very untypical, for conservativeness we include in our systematic budget the largest shifts seen in the NGC + SGC fit, namely those obtained with a covariance matrix based on EZ mocks without systematics (only the shuffled scheme, no syst. cov), i.e. 12.9 per cent on $f_{\sigma_8}$, 4.7 per cent on $\sigma_8$, and 1.2 per cent on $\alpha_{\perp}$.

Moving the centre of the $k$-bin by half a bin (0.005 h Mpc$^{-1}$) leads to a shift of 0.6 per cent for $f_{\sigma_8}$ and 0.2 per cent for $\sigma_8$ and $\alpha_{\perp}$. A larger $f_{\sigma_8}$ shift is observed for 393/1000 (considering both tails: 931/1000) EZ mocks, 463/1000 (884/1000) for $\sigma_8$, and 539/1000 (922/1000) for $\alpha_{\perp}$. As in Section 8.1, since these shifts are compatible with mocks, we do not include them in the systematic budget.

Changing the fiducial cosmology of equation (10) for the OuterRim cosmology of equation (34), we find moderate shifts of 6.0 per cent on $f_{\sigma_8}$, 1.2 per cent on $\sigma_8$, and 0.3 per cent on $\alpha_{\perp}$ (which are rescaled to the fiducial cosmology equation (10) for comparison purposes). Larger shifts are observed for 263/1000 (considering both tails: 349/1000) EZ mocks for $f_{\sigma_8}$, 283/1000 (474/1000) for $\sigma_8$, and 312/1000 (831/1000) for $\alpha_{\perp}$ and hence are fully compatible with a statistical fluctuation. Since we accounted for the change of fiducial cosmology in the systematic modelling budget, we do not quote any other related systematic uncertainty.

Figure 14. Combined RSD + BAO fit (left: NGC, right: SGC): data points with error bars from the EZ mocks and best-fitting model as continuous line for the power spectrum multipoles (top) and the BAO oscillation pattern (bottom), normalized residuals for every power spectrum multipole (middle).

Figure 15. Posteriors of the RSD and RSD + BAO measurements. Systematic uncertainties of Table 11 are not included.
The final error budget is reported in Table 11. The systematic bias related to the analysis methodology, namely the survey geometry, the RSD and BAO combination, the model non-linearity and the modelling of the ARIC are summed together in quadrature and added linearly to the statistical error bars. Other contributions are uncertainties due to our limited understanding of the ELG small-scale clustering (modelling systematics) or the survey selection function (photometric systematics, fibre collisions, redshift failures) or consist in analysis choices (damping term, covariance matrix, fiducial cosmology). These other terms are added in quadrature to the statistical error bars.

Including both statistical and systematic uncertainties, our final combined RSD + BAO measurement is (in the Bayesian case):

\[ f_{\sigma_8}(z_{\text{eff}} = 0.85) = 0.289^{+0.085}_{-0.096}, \]

\[ D_{\text{H}}(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 20.0^{+2.4}_{-2.2}, \]

\[ D_{\text{M}}(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 19.17 \pm 0.99. \]

(40)

As can be seen in Fig. 15, the linear bias combination \( b_8 \sigma_8 \) is correlated with \( f_{\sigma_8} \). Fixing \( \sigma_8 \) to the fiducial cosmology in equation (10), we find \( b_8^{\text{NCC}} = 1.49 \pm 0.10 \) and \( b_8^{\text{NGC}} = 1.52^{+0.10}_{-0.11} \), in agreement with previous studies (e.g. Comparat et al. 2013). Best-fitting values and errors for all parameters are given in Appendix D. No discrepancy can be seen between NCC and SGC nuisance parameters \( (b_8, \sigma_8, \alpha_8, \alpha_8) \). \( A_8^{\text{NCC}} \) and \( A_8^{\text{SGC}} \) are compatible with zero, as expected with nearly Poisson shot noise.

To include the systematic error budget in the above RSD + BAO posters, we rescale the distance of each MCMC sample \( (f_{\sigma_8}, \alpha_8, \alpha_{\perp}) \) to the median values by the ratio of total to statistical only errors. For example, the new \( f_{\sigma_8} \) position is

\[ \sigma_{f_{\sigma_8,\text{tot}}}/\sigma_{f_{\sigma_8,\text{stat}}} \ [f_{\sigma_8} - \text{median}(f_{\sigma_8})] + \text{median}(f_{\sigma_8}). \]

(41)

\[ \sigma_{f_{\sigma_8,\text{tot}}} \text{ and } \sigma_{f_{\sigma_8,\text{stat}}} \text{ are the upper (lower) total and statistical error bars with respect to the median when } f_{\sigma_8} > \text{median}(f_{\sigma_8}) \text{ (} f_{\sigma_8} < \text{median}(f_{\sigma_8})\text{)}. \]

We proceed similarly for \( \alpha_8 \) and \( \alpha_{\perp} \).

9 CONSENSUS

BAO and RSD analyses of the eBOSS ELG sample are also performed in configuration space, as detailed in Raichoor et al. (2020) and Tamone et al. (2020).

Post-reconstruction isotropic BAO measurements in Fourier and configuration space are compared for each mock in Fig. 16. Both measurements are well correlated \( (\rho = 0.8) \). Raichoor et al. (2020) measurement, \( D_{\text{H}}(z_{\text{eff}} = 0.845)/r_{\text{drag}} = 18.23 \pm 0.58 \) (statistical only) is < 0.2σ away from our Fourier space measurement, \( D_{\text{H}}(z_{\text{eff}} = 0.845) = 18.33^{+0.46}_{-0.52} \) (statistical only). A larger difference in the best fits occurs for 223/956 EZ mocks including all systematics (considering both tails: 648/1000), while we find 387/956 EZ mocks (considering both tails: 473/1000) with a larger difference in the mean of the lower and upper error bars. The good agreement between configuration and Fourier space measurements is shown by the data cross in Fig. 16, lying close to the diagonal. We choose the Fourier space measurement as consensus as it has a lower statistical uncertainty.

This measurement, \( D_{\text{H}}(z_{\text{eff}} = 0.845)/r_{\text{drag}} = 18.33^{+0.57}_{-0.62} \), is 0.6σ below the Planck Collaboration VI (2018) CMB-based (TT, TE, EE, lowE, lensing) prediction.

Combining RSD and BAO measurements in configuration space and including systematic uncertainties, Tamone et al. (2020) find

\[ f_{\sigma_8}(z_{\text{eff}} = 0.85) = 0.35 \pm 0.10, \]

\[ D_{\text{H}}(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 19.1^{+1.9}_{-2.0}, \]

\[ D_{\text{M}}(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 19.9 \pm 1.0. \]

(42)

These values are 0.7σ, 0.5σ, and 0.7σ away from our Fourier space median \( f_{\sigma_8}, D_{\text{H}}/r_{\text{drag}}, \) and \( D_{\text{M}}/r_{\text{drag}} \) values, respectively. Comparing the best fits instead, differences are 0.4σ, 0.4σ and 0.7σ, respectively. Again comparing best fits, larger differences occur in 386/1000 (considering both tails: 543/1000), 193/1000 (358/1000), and 246/1000 (311/1000) EZ mocks including all systematics. Considering posterior medians instead, larger differences occur in 158/1000 (considering both tails: 185/1000), 119/1000 (234/1000), and 256/1000 (324/1000) best fits to EZ mocks including all systematics. To combine these two measurements, since posteriors are not Gaussian but show comparable error bars, we translate them such that their two medians are located at the mean median and take the mean of the two posteriors as consensus. This method leads to an unbiased measurement if both measurements are unbiased, and is conservative about the final error bars. We show the two posteriors and their combination in Fig. 17. The consensus RSD + BAO eBOSS ELG measurement is thus

\[ f_{\sigma_8}(z_{\text{eff}} = 0.85) = 0.315 \pm 0.095, \]

\[ D_{\text{H}}(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 19.6^{+2.2}_{-2.1}, \]

\[ D_{\text{M}}(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 19.5 \pm 1.0. \]

(43)

These measurements are 1.4σ, 0.5σ, and 0.9σ from the Planck Collaboration VI (2018) CMB-based (TT, TE, EE, lowE, lensing) predictions for \( f_{\sigma_8}, D_{\text{H}}/r_{\text{drag}}, \) and \( D_{\text{M}}/r_{\text{drag}} \), respectively. We interpolate the consensus MCMC posterior (including systematic error bars) on a grid of \( f_{\sigma_8}, D_{\text{H}}/r_{\text{drag}}, \) and \( D_{\text{M}}/r_{\text{drag}} \) which is used, together with the BAO likelihood profile (including systematic error bars), for the combined eBOSS cosmological constraints presented in eBOSS Collaboration (2020).

10 CONCLUSIONS

In the above, together with Raichoor et al. (2020) and Tamone et al. (2020), we presented the first measurement of the pre-reconstruction RSD and post-reconstruction BAO signal in the eBOSS ELG sample.

We started by testing our implementation of the RSD TNS (Taruya et al. 2010) model and isotropic BAO template using N-body based simulations. These models proved robust enough for our analysis. However, this analysis was complicated by various observational and analysis artefacts.

First, the fine-grained veto masks applied to the eBOSS ELG data led us to revise the way window functions are normalized in the model. We also noticed that measuring the expected redshift distribution from observed data itself (using the shuffled scheme) led to a significant bias of cosmological parameters, which we corrected by modelling the induced RIC as in de Mattia & Ruhlmann-Kleider (2019). Fibre collisions have been found to have a moderate impact, which we modelled following Hahn et al. (2017). Finally, residual angular systematics due to the inhomogeneous photometry, which could not be treated following the standard technique of template regression, were mitigated using the pixelated scheme as discussed in de Mattia & Ruhlmann-Kleider (2019).
errors, taken to be the mean of the upper and lower error bars). The red cross shows the eBOSS ELG data.

Post-reconstruction isotropic BAO measurements in the EZ mocks including all systematics, in Fourier and configuration space (left: best fits, right: data).

Table 11. Error budget for RSD + BAO measurements on the eBOSS DR16 ELG sample. Percentages are provided with respect to the parameter value. The last three lines (statistics, systematics, and total) recap the absolute statistical error bar, the systematic contribution (total minus statistics), and the total error bar, respectively.

| Source                        | $f\sigma_8$  | $\alpha_w$  | $\alpha_z$  |

Figure 16. Post-reconstruction isotropic BAO measurements in the EZ mocks including all systematics, in Fourier and configuration space (left: best fits, right: errors, taken to be the mean of the upper and lower error bars). The red cross shows the eBOSS ELG data.

For this study, to test our analysis pipeline, we implemented the survey geometry and realistic systematics into mock catalogues: depth-dependent radial selection function, angular photometric systematics, fibre collisions and redshift failures. We proved on mocks that our analysis is robust to these systematics when including all the corrections mentioned above. We derived residual systematic uncertainties from both our mock studies and robustness tests run on data.

As another extension over previous work, we combined RSD and post-reconstruction BAO measurements at the likelihood level to avoid assuming them Gaussian and strengthen our cosmological measurements.

Taking into account statistical and systematic uncertainties, the post-reconstruction isotropic BAO analysis in Fourier space provides a measurement of the ratio of the volume-averaged distance to the sound horizon at the drag epoch:

\[
D_v(z_{\text{eff}} = 0.845)/r_{\text{drag}} = 18.33^{+0.57}_{-0.62},
\]

which is the BAO consensus measurement of the eBOSS ELG sample. The Fourier space RSD + BAO measurement, including statistical and systematic uncertainties, is

\[
f\sigma_8(z_{\text{eff}} = 0.85) = 0.289^{+0.085}_{-0.096},
\]

\[
D_H(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 20.0^{+2.4}_{-2.2},
\]

\[
D_M(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 19.17 \pm 0.99.
\]

Combined with configuration space results of Tamone et al. (2020), we find

\[
f\sigma_8(z_{\text{eff}} = 0.85) = 0.315 \pm 0.095,
\]

\[
D_H(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 19.6^{+2.1}_{-2.1},
\]

\[
D_M(z_{\text{eff}} = 0.85)/r_{\text{drag}} = 19.5 \pm 1.0.
\]

Some observational systematics may remain, due to our incomplete understanding of the relation between the ELG target density and the imaging properties in the early DECaLS release used in the eBOSS ELG target selection. We note that DESI (DESI Collaboration 2016) will target ELG with the Legacy Imaging Surveys (Dey et al.
2019) that includes DECaLS. Though this latest photometric survey is deeper and more isotropic, fainter ELG targets are targeted, such that one may expect significant 3-dimensional fluctuations of the survey selection function due to photometric variations as seen in the eBOSS ELG sample. Understanding these fluctuations will be key to the clustering analysis of the DESI ELG sample.

In conclusion, this work was the opportunity to deal with analysis systematics (impact of fixing the template cosmology, ICs) and observational systematics (three-dimensional fluctuations of the survey selection function) which were not fully tackled in previous SDSS clustering analyses and are of importance for the next generation of spectroscopic surveys, including DESI (DESI Collaboration 2016) and Euclid (Laureijs et al. 2011).

Appendix A: Covariance Corrections

In this section, we justify the corrections applied to the parameter covariance for our combined NGC and SGC cosmological fit. Formula equation (28) is (formally) incorrect when combining two independent Gaussian likelihoods (e.g. NGC and SGC). Indeed, an intuitive use of equation (28) would take $n_p$ as the number of bins in either NGC or SGC and $n_b$ the total number of parameters. Then, however, the constraint $n_p \leq n_b$ inherent to this formula appears artificial. Indeed, there is no issue with having $n_p > n_b$ as long as...
where \( n_b \) is less than the total number of bins. Another approach would be to take \( n_b \) as the total number of bins in NGC and SGC; though this would be correct if we estimated the combined NGC and SGC covariance from mocks, this does not apply to our case where we impose the cross-covariance between NGC and SGC to be zero. Therefore, we have to derive equation (28) in the context of a block-diagonal covariance matrix.

The Hartlap (Hartlap et al. 2007) correction is applied to the inverse NGC covariance matrix to obtain the precision matrix:

\[
\hat{\psi}_{\text{NGC}} = (1 - D_{\text{NGC}}) (C_{\text{NGC}})^{-1}, \quad D_{\text{NGC}} = \frac{n_b^{\text{NGC}} + 1}{n_m^{\text{NGC}} - 1},
\]

with \( n_b^{\text{NGC}} \) the number of bins and \( n_m^{\text{NGC}} \) the number of mocks in NGC; similarly for SGC. The full precision matrix \( \Psi \) is a block-diagonal matrix built from \( \hat{\psi}_{\text{NGC}} \) and \( \hat{\psi}_{\text{SGC}} \). To obtain the corrections to the parameter covariance the errors on each precision matrix must be propagated through the Fisher information. The estimator for parameter \( p_{\alpha} \), whose true value is assumed to be zero without loss of generality, is (equation 24 in Dodelson & Schneider 2013)

\[
\hat{p}_\alpha = [F + \Delta F]^{-1} \frac{\partial x^\prime_i}{\partial p_\alpha} \hat{\psi}_{\alpha} \left( x^\prime_i - x^\prime_i \right),
\]

where \( x^\prime_i \) and \( x^\prime_i = \langle x^\prime_i \rangle \) are the data measurement and its true value. \( F_{\alpha\beta} \) is the true Fisher matrix:

\[
F_{\alpha\beta} = \frac{\partial x^\prime_i}{\partial p_\alpha} \frac{\partial x^\prime_i}{\partial p_\beta},
\]

with \( \hat{\psi} = (C)^{-1} \) the true inverse covariance matrix and similarly

\[
\Delta F_{\alpha\beta} = \frac{\partial x^\prime_i}{\partial p_\alpha} \Delta \psi_{ij} \frac{\partial x^\prime_i}{\partial p_\beta},
\]

with \( \Delta \psi_{ij} = \psi_{ij} - \psi_{ij} \). Then, Dodelson & Schneider (2013) recall that the leading order parameter covariance is \( \langle \hat{p}_\alpha \hat{p}_\beta \rangle \propto F_{\alpha\beta}^{-1} \) and derive the next-to-leading (second-order) contribution:

\[
\langle \hat{p}_\alpha \hat{p}_\beta \rangle \propto F_{\alpha\beta}^{-1} \left[ \frac{\partial x^\prime_i}{\partial p_\alpha} \frac{\partial x^\prime_i}{\partial p_\beta} \right] \left( \frac{\partial \hat{\psi}_{ij}}{\partial p_\alpha} (\Delta \psi)_{ij} (\Delta \psi)_{ij} \right) F_{\beta\beta}^{-1}
\]

\[
- \left( F^{-1} \Delta FF^{-1} \Delta F^{-1} \right)_{\alpha\beta}.
\]

Similarly to Taylor, Joachimi & Kitching (2013) and Dodelson & Schneider (2013), we write the covariance of the precision matrix fluctuations as

\[
\langle \Delta \psi_{ij} \Delta \psi_{j'i'} \rangle = \left( A_{\text{NGC}}^{ij} + A_{\text{SGC}}^{ij} \right) \psi_{ij} \psi_{j'i'}.
\]

\[
+ \left( B_{\text{NGC}}^{ij} + B_{\text{SGC}}^{ij} \right) \left( \psi_{ij} \psi_{j'i'} \psi_{ij} \psi_{j'i'} \right),
\]

where \( A_{ij}^{jj'} \) is constant (equal to \( A^{\text{NGC}} \)) if indices \( jj' \) all lie in the same block NGC, zero elsewhere (i.e. cross-covariance terms between NGC and SGC are zero), and similarly for SGC and B terms. We recall that

\[
A^{\text{NGC}} = \frac{2}{(n_m^{\text{NGC}} - n_b^{\text{NGC}} - 1) (n_m^{\text{NGC}} - n_b^{\text{NGC}} - 4)},
\]

\[
B^{\text{NGC}} = \frac{2}{(n_m^{\text{NGC}} - n_b^{\text{NGC}} - 1) (n_m^{\text{NGC}} - n_b^{\text{NGC}} - 4)},
\]

and similarly for SGC. Let us consider the contribution from the A terms first. From equation (A5), one gets the contribution:

\[
\langle \hat{p}_\alpha \hat{p}_\beta \rangle \propto F_{\alpha\beta}^{-1} \left[ A^{\text{NGC}} F_{\alpha'\beta'}^{\text{NGC}} + A^{\text{SGC}} F_{\alpha'\beta'}^{\text{SGC}} \right] F_{\beta\beta}^{-1},
\]

where we split the total Fisher information \( F = F^{\text{NGC}} + F^{\text{SGC}} \) (since NGC and SGC are independent). Equation (A6) gives

\[
\langle \hat{p}_\alpha \hat{p}_\beta \rangle \propto -F_{\alpha'\beta'}^{-1} F_{\alpha'\beta'}^{-1} \left( A^{\text{NGC}} F_{\alpha'\beta'}^{\text{NGC}} + A^{\text{SGC}} F_{\alpha'\beta'}^{\text{SGC}} \right).
\]

Let us move to the B terms. From equation (A5), one gets the contribution:

\[
\langle \hat{p}_\alpha \hat{p}_\beta \rangle \propto F_{\alpha'\beta'}^{-1} \left[ B^{\text{NGC}} \left( n_b^{\text{NGC}} + 1 \right) F_{\alpha'\beta'}^{\text{NGC}} \right] F_{\beta\beta}^{-1},
\]

and from equation (A6):

\[
\langle \hat{p}_\alpha \hat{p}_\beta \rangle \propto -F_{\alpha'\beta'}^{-1} F_{\alpha'\beta'}^{-1} \left( B^{\text{NGC}} F_{\alpha'\beta'}^{\text{NGC}} + B^{\text{SGC}} F_{\alpha'\beta'}^{\text{SGC}} \right).
\]

Formulae above could be evaluated numerically, but we will consider a simpler case in the following. We assume that \( F_{\alpha'\beta'}^{\text{NGC}} \) and \( F_{\alpha'\beta'}^{\text{SGC}} \) are block-diagonal, with specific parameters for NGC and SGC which are uncorrelated, and a set of common parameters \( \alpha \beta \) for which the Fisher information content can be written \( F^{\text{NGC}} = f^{\text{NGC}} F_{\alpha'\beta'} \) (respectively \( F^{\text{SGC}} = f^{\text{SGC}} F_{\alpha'\beta'} \)), with \( \rho^{\text{NGC}} + \rho^{\text{SGC}} = 1 \). We also assume the common parameters to be uncorrelated to the NGC and SGC specific parameters. Then, the contribution from the A and B terms to the covariance of the common parameters is simply the sum of terms \( C_1 \) (from equation (A5)) and \( C_2 \) (from equation (A6)):

\[
\langle \hat{p}_\alpha \hat{p}_\beta \rangle \propto \left[ C_1^{\text{NGC}} + C_1^{\text{SGC}} - C_2^{\text{NGC}} - C_2^{\text{SGC}} \right] F_{\alpha'\beta'}^{-1}
\]

where

\[
C_1^{\text{NGC}} = A^{\text{NGC}} f^{\text{NGC}} + B^{\text{NGC}} f^{\text{NGC}} (n_b^{\text{NGC}} + 1)
\]

and

\[
C_2^{\text{NGC}} = A^{\text{NGC}} (f^{\text{NGC}})^2 + B^{\text{NGC}} f^{\text{NGC}} (n_b^{\text{NGC}} + f^{\text{NGC}}),
\]

where we use the effective number of parameters \( n_{\text{eff}}^{\text{NGC}} = n_b^{\text{NGC}} + f^{\text{NGC}} \), with \( n_b^{\text{NGC}} \) the number of parameters specific to NGC (similarly for SGC) and \( n_{\text{eff}} \) the number of parameters in common. The contribution to the covariance of the specific parameters is obtained for e.g. NGC by forcing \( \hat{p}^{\text{SGC}} = 0 \) (then \( p^{\text{SGC}} = 0 \)) and keeping \( n_{\text{eff}}^{\text{NGC}} \) fixed. In this case, errors from the NGC precision matrix only contribute to the parameter covariance. In the simplified case where \( n_{\text{eff}} = 0 \), the known result of Dodelson & Schneider (2013)

\[
\langle \hat{p}_\alpha \hat{p}_\beta \rangle \propto B^{\text{NGC}} \left[ n_b^{\text{NGC}} - n_b^{\text{SGC}} \right] F_{\alpha\beta}^{-1}
\]

is recovered. Adding up A and B contributions, the parameter covariance is

\[
V_{\alpha\beta} = \left[ 1 + C_1^{\text{NGC}} + C_1^{\text{SGC}} - C_2^{\text{NGC}} - C_2^{\text{SGC}} \right] F_{\alpha\beta}^{-1}.
\]

The parameter variance estimated from the likelihood is (equation 16 in Percival et al. 2014)

\[
\sigma_{\alpha\beta} = \left( F + \Delta F \right)^{-1}_{\alpha\beta},
\]

whose second-order term is just equation (A6) (equation 15 in Percival et al. 2014). Then

\[
\sigma_{\alpha\beta}^2 = \left[ 1 + C_2^{\text{NGC}} + C_2^{\text{SGC}} \right] F_{\alpha\beta}^{-1}.
\]

[12] This is of course not the case in practice.
Therefore, the full correction to apply to the parameter covariance estimated from the likelihood is

$$m_1 = \frac{V_{\alpha\beta}}{\sigma_{\alpha\beta}} = \frac{1 + C_1^{NGC} + C_1^{SGC} - C_2^{NGC} - C_2^{SGC}}{1 + C_1^{NGC} + C_1^{SGC}}. \quad (A22)$$

As noted by Percival et al. (2014), in case the mocks used to produce the covariance matrix are fitted, the covariance of the measurements $x_i$ is just $C_{ij}$:

$$\langle (x_i^d - x_i^f) (x_j^d - x_j^f) \rangle = C_{ij} \quad (A23)$$

and

$$= (1 - D_{ij}^{NGC}) \Psi_{ij}^{-1} + (1 - D_{ij}^{SGC}) \Psi_{ij}^{-1}, \quad (A24)$$

where $D_{ij}^{NGC} = D_{ij}^{SGC}$ if $ij$ lie in the NGC block, zero otherwise, and similarly for SGC. Then

$$\langle \hat{p}_i \hat{p}_j \rangle = [P + \Delta P]_{\alpha\beta}^{-1} \left\{ (1 - D_{ij}^{NGC}) \Psi_{ij}^{-1} \Psi_{ij} \Psi_{ij}^{-1} (1 - D_{ij}^{SGC}) \Psi_{ij}^{-1} \right\} \quad (A25)$$

$$\Psi_{ij} \Psi_{ij}^{-1} \langle (x_i^d - x_i^f) (x_j^d - x_j^f) \rangle \quad (A26)$$

$$= [P + \Delta P]_{\alpha\beta}^{-1} \left\{ (1 - D_{ij}^{NGC}) \Psi_{ij}^{-1} \Psi_{ij} \Psi_{ij}^{-1} (1 - D_{ij}^{SGC}) \Psi_{ij}^{-1} \right\} \quad (A27)$$

$$= [P + \Delta P]_{\alpha\beta}^{-1} \left\{ (1 - D_{ij}^{NGC}) \Psi_{ij}^{-1} \Psi_{ij} \Psi_{ij}^{-1} (1 - D_{ij}^{SGC}) \Psi_{ij}^{-1} \right\} \quad (A28)$$

$$= [P + \Delta P]_{\alpha\beta}^{-1} \left\{ (1 - D_{ij}^{NGC}) \Psi_{ij}^{-1} \Psi_{ij} \Psi_{ij}^{-1} (1 - D_{ij}^{SGC}) \Psi_{ij}^{-1} \right\} \quad (A29)$$

Hence, the covariance of best-fitting parameter values obtained from the mocks should be rescaled by

$$m_2 = \frac{V_{\alpha\beta}}{\sigma_{\alpha\beta}} = \frac{V_{\alpha\beta}}{\sigma_{\alpha\beta}} \quad (A30)$$

$$= m_1 \left\{ (1 - D_{ij}^{NGC}) \Psi_{ij}^{-1} \Psi_{ij} \Psi_{ij}^{-1} (1 - D_{ij}^{SGC}) \Psi_{ij}^{-1} \right\}^{-1}, \quad (A31)$$

to be compared with the parameter covariance derived from the likelihood [applying the Harlap factor of equation (A1) and $m_1$ of equation (A22)].

**APPENDIX B: EFFECTIVE REDSHIFT**

In this section, we derive another definition of the effective redshift, more specific to the Fourier space analysis.

With the Yamamoto estimator, in the local plane-parallel approximation, assuming the (perfectly known) survey selection function varies slowly compared to the correlation function, and with infinite $d\Omega$ sampling we measure (in average)

$$\langle \hat{P}_i(k) \rangle = \frac{\int d^3r \tilde{n}(r)P(k, z) }{\int d^3r \tilde{n}(r)}, \quad (B1)$$

where $\tilde{n}(r)$ is the expected mean density of weighted galaxies in the absence of clustering and $P_i(k, z)$ is the true galaxy power spectrum at redshift $z$. Taylor expanding the power spectrum about the effective redshift $z_{\text{eff}}$:

$$P_i(k, z) = P_i(k, z_{\text{eff}}) + P_i'(k, z_{\text{eff}})(z - z_{\text{eff}}) + \cdots \quad (B2)$$

and substituting this expression into equation (B1), we find that the expected value of the Yamamoto estimator can be approximated at first order by the quantity that we actually model:

$$\langle \tilde{P}_i(k) \rangle = \frac{\int d^3r \tilde{n}(r)P_i(k, z_{\text{eff}}) }{\int d^3r \tilde{n}(r)}, \quad (B3)$$

if we use the effective redshift:

$$z_{\text{eff}} = \frac{\int d^3r \tilde{n}(r)z(r) }{\int d^3r \tilde{n}(r)} \approx \sum_{i=1}^N w_{\text{det}} n_{\text{det}} z_i \sum_{i=1}^N w_{\text{det}} n_{\text{det}} \quad (B4)$$

We checked that the value obtained with this definition of the effective redshift agrees with equation (36) to the 0.5 per cent level.

**APPENDIX C: COUPLING BETWEEN DATA AND COVARIANCE MATRIX**

Some concern may be raised about a possible coupling between the data power spectrum measurements and the covariance matrix built from the 1000 EZ mocks. Indeed, angular systematics were implemented in these mocks based on a map of the observed ELG density (smoothed by a Gaussian beam of radius 1 deg). By construction, this systematic map includes data clustering angular modes which diffuse in the clustering of the contaminated EZ mocks. To check the importance of this effect, we generate a new systematic map based on the angular target density measured on the observed mock, we find small shifts in SGC RSD fits of 1 per cent for $f_{\sigma}^{\delta}$, 0.2 per cent for $\alpha_{\sigma}$, and 0.3 per cent for $\alpha_{\delta}$, which are not significant since larger shifts are seen in 116/999, 471/999, and 440/999 EZ mocks (considering both tails: 219/999, 901/999, and 783/999).

Redshift failures are also implemented in the mocks based on the observed data. We check the potential bias due to this tuning following the same procedure as for photometric systematics. With both photometric and redshift failures coming from one mock, we find small shifts in SGC RSD fits of 1.9 per cent for $f_{\sigma}^{\delta}$, 1.2 per cent for $\alpha_{\sigma}$, and 0.3 per cent for $\alpha_{\delta}$, which are again not significant since larger shifts are seen in 279/999, 257/999, and 418/999 EZ mocks (considering both tails: 498/999, 463/999, and 783/999). We therefore see no evidence for a systematic bias due to coupling between data measurements and the covariance matrix built from contaminated EZ mocks.

**APPENDIX D: RSD + BAO FULL BEST FIT**

We report all RSD + BAO best-fitting parameters to eBOSS ELG NGC + SGC in Table D1.
Table D1. Parameters for the eBOSS ELG combined RSD + BAO likelihood. We provide the best fit, as well as the mean and the median of the MCMC samples. Error bars are given around the best fit. The \( \Delta \chi^2 = 1 \) errors in parameter \( x \) are given by the \( x \) values for which \( \chi^2 \) is increased by 1 compared to the best fit, when minimizing with respect to all other parameters. The 68 per cent interval for parameter \( x \) corresponds to the smallest interval of \( x \) which contains 68 per cent of the MCMC samples. We also quote the standard deviation of the MCMC samples. The [16 per cent, 84 per cent] interval is given by the 16 per cent and 84 per cent percentiles of the MCMC samples. Systematic uncertainties of Table 11 are not included.

| Parameter       | Best fit | Mean  | Median | \( \Delta \chi^2 = 1 \) | 68 per cent interval | Standard deviation | [16 per cent, 84 per cent] interval |
|-----------------|----------|-------|--------|-------------------------|----------------------|-------------------|-----------------------------------|
| \( f_{g} \)    | 0.289    | 0.282 | 0.281  | \( +0.068 \)             | \( +0.069 \) to \( +0.061 \) | 0.067             | \( +0.061 \) to \( -0.074 \) |
| \( \alpha_{+} \)| 1.085    | 1.082 | 1.089  | \( -0.066 \)             | \( -0.067 \) to \( -0.062 \) | 0.103             | \( -0.062 \) to \( -0.102 \) |
| \( \alpha_{-} \)| 0.941    | 0.942 | 0.940  | \( -0.034 \)             | \( -0.035 \) to \( -0.033 \) | 0.061             | \( -0.033 \) to \( -0.039 \) |
| \( \sigma_{S_{G}} \) | 0.779   | 0.770 | 0.774  | \( +0.044 \)            | \( +0.043 \) to \( +0.042 \) | 0.046             | \( +0.035 \) to \( +0.053 \) |
| \( \sigma_{S_{C}} \) | 0.795   | 0.782 | 0.787  | \( -0.079 \)            | \( -0.078 \) to \( -0.077 \) | 0.045             | \( -0.077 \) to \( -0.057 \) |
| \( \sigma_{N_{G}} \) | -0.23   | -0.14 | -0.18  | \( +0.97 \)             | \( +0.96 \) to \( +0.95 \) | 0.72              | \( +0.95 \) to \( -0.87 \) |
| \( \sigma_{N_{C}} \) | -0.1    | -0.01 | -0.02  | \( +0.12 \)             | \( +0.11 \) to \( +0.10 \) | 0.79              | \( +0.10 \) to \( +0.81 \) |
| \( \sigma_{A_{S}} \) | 0.02    | 0.04  | 0.01   | \( +0.24 \)             | \( +0.24 \) to \( +0.23 \) | 0.17              | \( +0.20 \) to \( +0.13 \) |
| \( \sigma_{A_{G}} \) | -0.04   | 0.02  | -0.04  | \( +0.35 \)             | \( +0.35 \) to \( +0.34 \) | 0.20              | \( +0.34 \) to \( +0.26 \) |
| \( \nu_{S_{G}} \) | 2.53    | 2.14  | 2.23   | \( +0.73 \)             | \( +0.72 \) to \( +0.71 \) | 0.94              | \( +0.54 \) to \( -1.11 \) |
| \( \nu_{S_{C}} \) | 3.05    | 2.73  | 2.81   | \( +0.73 \)             | \( +0.72 \) to \( +0.71 \) | 0.88              | \( +0.51 \) to \( -1.16 \) |
