Abstract

In satellite technology, the communication between space segment and ground segment plays a vital role in the success of the mission. This paper is targeted at study, design and fabrication of a microwave active filter for the receiver front-ends using coupled line filter structure, which can be applied to the nanosatellite’s communication subsystem. The whole active filter module is a combination of a microstrip bandpass filter and a preceding two-stage wideband low noise amplifier using FET devices. The proposed module operates in the frequency range of 2-2.4 GHz, which can be divided to 10 frequency slots of about 40 MHz for each. These frequency slots will be used for the S-band multi-frequency receiving function of the ground station, as well as the nanosatellite. The simulated and measured results of this active filter configuration are presented.

Keywords: coupled line bandpass filter, microwave active filter, nanosatellite, receiver front-ends, wideband low noise amplifier

1. Introduction

Small satellites have been widely applied in communications satellite in recent years. In this section, nanosatellite is being regarded as a proper choice for satellite communication in developing countries, because of its low fabrication budget, ability of integrating numerous in a single launch vehicle, and the possible of arranging in constellation for in-situ operation. The wet mass of a typical nanosatellite lies between 1 and 10 kg, and its dimensions seldomly exceed 30 cm. The performance of receiver system for nanosatellite missions is mainly governed by the bandpass filter (BPF) and low noise amplifier (LNA) units. Without these parts, the receiver is unable to distinguish the weak receiving signal from the noise. Consequently, the bit error rate (BER) will increase drastically and certainly lower the quality of the receiving message. Therefore, designing good filtering and low noise amplifying modules are prime requirements of a success communication mission.

In the filter region, there are four major parameters govern the dissipation loss level of a bandpass filter: The filter type, the order of the filter, the unloaded Q-factor of the filter elements and the bandwidth. Universally, all passive bandpass filtering structures encounter a problem of compromising between insertion loss and bandwidth, especially at radiofrequency. For details, the product of these two parameters is a constant [1], a narrower bandpass filter means higher degree of insertion loss. Furthermore, in microwave frequencies, it is really a challenge to construct a high-performance filter with passive elements only, because of the detrimental effects of the parasitic elements. Electronics researchers have taken many efforts to deal with these problems for decades, and thanks to the development of the semiconductor technology, a very promising solution for this limitation is established: Using field affect transistors (FET) as active elements to compensate the insertion loss while maintaining the bandwidth quality of the filter. The system consists of the microwave filter and the active element, which is the LNA in our case, is called Microwave Active Filter (MAF). The receiving signals first go through a bandpass filter, which lies outside the MAF unit, for a primary filtering process. This filter is necessary because the raw receiving signal is very noisy and contains some amplitude perturbation superimposing components, which can lead to an overload in the LNA. Figure 1 shows the block diagram of a receiver system including the MAF unit:

Received May 28, 2018; Revised September 27, 2018; Accepted November 28, 2018
After being filtered, the signals enter the MAF unit and being amplified to a desired amplitude level by the LNA, then go through the BPF of the MAF for a smooth filtering process. Subsequently, at the input of the mixer of the IF stage, we have low noise, well-amplified signals at the desired RF band. There are previous works related to MAF. In their electronics letter, Chang and Itoh [2] published a narrowband MAF using microstrip distributed elements, based on the coupled negative resistance method. R. Gracia and J. Alonso [3] demonstrated a high-selective microwave active bandpass filter using transmission line interference sections with a passive filter precedes an active interference stage. Though these topologies showed good results at S-band, it is fairly difficult to put them into application of a high order microstrip filter for a nanosatellite receiver because of its complexity. Cheng et al. (2000) published a novel way to increase the linearity and noise performance of microwave active bandpass filters using the negative-resistance compensated topology [4]. A structure includes an LNA and a bandpass filter called as the Selective RF Low Noise Amplifier, which can be used in FM broadcast band (88–108 MHz), is introduced by Lee and Lu [5]. An active 8-path filter with a preceding LNA for software-defined radio (SDR) transceivers, in which the center frequency can be tuned from 100 MHz to 2 GHz is presented by Behmanesh and Atarodi [6]. L. Pantoli et al. [7] illustrated a tunable active filter topology for microwave applications. However, these mentioned works used lumped filter elements and can only be effectively applied for the frequency range of below 2 GHz, it is fairly difficult to apply these designs in the frequency range of over 2 GHz when taking the dissipation loss and parasitic effects into account, especially when integrating them in a satellite that operating in a harsh environment. Mariem and Nabih [8] designed an active bandpass filter based on operational transistor amplifiers using simple CMOS current mirrors, this filter structure has very good return loss ($S_{11}$) and insertion loss ($S_{21}$) responses and can also be tuned to operate at the frequency range of about 2 GHz by modifying the value of the grounded capacitor and inductor of this topology. However, the passband bandwidth is very narrow (about 15 MHz) and it might not suitable for our mission. Y. Hao et al. mentioned a MAF solution for satellite’s receiver front-ends by placing a bandpass filter in front of the LNA to choose the desired frequency band and reduce the noise, which is very similar to our method [9]. However, the authors only demonstrated the filter design process and optimized the results by using Advance Design System (ADS) but ignore the role of the LNA. Furthermore, the filter design of the authors seemed not to be practical enough to apply to a real satellite front-end receiver.

Our designing purpose is to obtain the best trade-off between operation frequency, total efficiency of the system, and simplicity. The key features of the proposed MAF are listed below:

- Has a relative high gain and low noise figure.
- Provides least distortion to the frequency response.
- Has the ability of tuning frequency in a wide range at S-band. In our case, the entire range is from 2 GHz to 2.4 GHz with 10 internal frequency slots.
- Compact enough to be integrated to the receiver system in either space segment (nanosatellites) or earth segment (small ground stations).

2. Design and Simulation of the Coupled Line Bandpass Filter

The microstrip coupled line bandpass filter is widely used in radiofrequency, because of its equilibrium between performance, simplicity and manufacturing expenses. Similar to a single microstrip line, a coupled microstrip line is a quasi-TEM mode system with no cut-off frequency. For microwave frequency, the filtering topology using microstrip distributed elements have many benefits over the lumped elements topology, such as reduces the parasitic effects, easier to...
produce, and offers much smaller area and profile. In the microstrip coupled lines, there are two different modes of field distribution, namely the odd-mode and even-mode, which can be physically explained by the positions of the relative polarities of voltages along the transmission lines. Consequently, it leads to the two characteristic impedances called the odd-mode characteristic impedance ($Z_{0o}$) and even-mode characteristic impedance ($Z_{0e}$), which are the two primary parameters in the design procedure [10]. Figure 2 demonstrates the field distribution of these two modes:

![Field Distribution Odd and Even Modes](image)

Figure 2. The field distribution over odd and even modes of the coupled lines [10]

A half-wavelength parallel coupled line microstrip bandpass filter is a structure included coupled lines which are paralleled in pairs along half of their lengths. Once appropriately spacing the resonator elements, we have a good coupling, thus providing the desired bandwidth. The spacing parameters (or gaps) are denoted by $S$. Along with the gap, there are other governing parameters, namely length ($l$), width ($W$) and characteristic admittance ($Y_0$), which is just the inverse of the characteristic impedance, $Z_0$, of the connecting line. The filter structure is demonstrated in Figure 3:

![Filter Structure](image)

Figure 3. The structure of the microstrip parallel coupled line bandpass filter (redrawn from [11])

the following equations are used to design the filter:

$$J_{0,1}Z_0 = \frac{\pi f BW}{2g_{0g1}}$$  \hspace{1cm} (1)
\[ J_{j,j+1}Z_0 = \frac{\pi FBW}{\sqrt{g_j}} \quad \text{for} \ j=1 \text{ to } n-1 \]  

\[ J_{n,n+1}Z_0 = \sqrt{\frac{\pi FBW}{g_n}} \]  

where \( g_0, g_1, \ldots, g_n \) are element values, in our case: \( g_0 = g_4 = 1, g_1 = g_3 = 1.5963, g_2 = 1.0967 \). FBW is the filter’s fractional bandwidth. \( Z_0 \) is the characteristic impedance of the line, as explained before and \( J \) (with subscribes) is the characteristic admittances of the inverters. Based on the above equations, we can calculate the characteristic impedances of the odd and even modes of the parallel coupled line microstrip bandpass filter as follows [12]:

\[ (Z_{0,0})_{j,j+1} = Z_0(1 - J_{j,j+1}Z_0 + (J_{j,j+1}Z_0)^2) \]  

\[ (Z_{0,0})_{j,j+1} = Z_0(1 + J_{j,j+1}Z_0 + (J_{j,j+1}Z_0)^2) \]

in this design, we chose the 3rd order filter with 2 pairs of symmetric filter elements. The calculated values (in Ohms) of the characteristic impedances are shown in Table 1:

| Filter stage | Odd mode impedance \((Z_{0o})\) | Even mode impedance \((Z_{0e})\) |
|--------------|-------------------------------|-------------------------------|
| 0            | 51.68                         | 79.57                         |
| 1            | 46.47                         | 89.76                         |

The material used for the filter structure is Rogers FR4, which has the following characteristics: Relative dielectric constant: 4.34, loss tangent: 0.0025, dielectric height: 1.6 mm, conductor thickness: 0.035 mm, roughness: 0.0095. The simulated results in Decibel of the input reflection coefficient \((S_{11})\) and insertion loss \((S_{21})\) have been done by the Advanced Design System (ADS) 2014, provided by Agilent. The schematic design and simulated results are illustrated in Figure 4.

The results are simulated based on the formulae from (1) to (5), without abusing the Optimization Tool of the ADS software, because this type of tool might lead to nonreproducible and non-systematic solutions [13]. As can be seen in Figure 5, the insertion loss \((S_{21})\) and return loss \((S_{11})\) is around 0.95 dB and 21.60 dB at 2.25 GHz, respectively. Furthermore, the ripple in the whole passband is rounded 0.7 dB and the 3 dB bandwidth is approximately 250 MHz. This result is not suitable to apply to the total frequency range of 400 MHz of our desired receiver.
Research, design and fabrication of a microwave active filter for... (Linh Ta Phuong)
The LNA network can only work efficiently once being impedance matched properly in both of its input and output. The purpose of impedance matching is to maximize the transferred power from the source to the load and minimized the reflected power from the load to the source, thus optimize the voltage standing wave ratio (VSWR). The figure below demonstrates a typical matching system, which includes input and output matching networks for a single stage of our LNA.

In Figure 7, $Z_S$ needs to be matched with $Z_L$, and these parameters both equal 50 Ohms, which is the characteristics impedance ($Z_0$) of the transmission lines. In order to reach this, the values of the reflection coefficients of the input and output matching networks, namely $\Gamma_S$ and $\Gamma_L$, need to be equalized to the corresponding reflection coefficients of the input and output, $\Gamma_{IN}$ and $\Gamma_{OUT}$, of the LNA. Once the input and output of the LNA are both being matched, we can calculate the available power gain of the LNA, which is the ratio of the power available from the amplifier to the power available from the source [16]. The proposed LNA has the same structure as shown in Figure 8, with the desired bandwidth of 400 MHz and the operation center frequency of 2.3 GHz. The figure below is the schematic diagram of the 2-stage wideband LNA, using the same FR4 substrate as that of the previous coupled line BPF.

![Figure 7. The diagram of impedance matching networks of the single stage of the LNA](image)

As can be seen in the above Figure 8, the two stages are identical to each other. A 10 pF capacitor has been placed between the two stages in order to reduce the parasitic effect. The impedance matching technique used here is the combination of general and quarter-wave transmission lines. The quarterwave transformers are TL3, TL4, TL15 and TL16, respectively. The center frequencies of both stages are 2.3 GHz. The typical power supply of the SPF-2086 transistors are 5 V/50 mA and the biasing point is reached at-0.5 V. Figure 9 displays the simulated gain and input reflection coefficient of the 2-stage LNA:

![Figure 8. Schematic diagram of the 2-stage cascaded LNA](image)
It is clearly see that in Figure 9, the overall gain ($S_{21}$) is greater than 35 dB at the frequency range of 2.15–2.58 GHz, the maximum gain of 38.57 dB is obtained at 2.51 GHz. The input reflection coefficient, $S_{11}$, is approximately -9.6 dB at the desired frequency, which lies in the tolerance range.

![Figure 9. The simulated result of the 2-stage wideband LNA](image)

4. Measured Results
The whole MAF circuit was successfully designed and fabricated in our laboratory based on the ADS package and the LPKF Promomat C40 machine. The testing results of the filter without connecting to the LNA are measured on the Vector Network Analyzer 37369D-Anritsu technology with the linearity range up to 40 GHz. Figure 10 and Figure 11 show the experimental results of the coupled line microstrip bandpass filter without LNA. As can be seen in these below figures, the experimental results are well matched to the simulated results showed in Figure 5. Particularly, in Figure 10, the insertion loss ($S_{21}$) peaked at around 2.25 GHz and the degrade of $S_{21}$ is caused by cables and connectors’ loss, which has the value of approximately 2.3 dB.

![Figure 10. The measured $S_{21}$ of the parallel coupled line microstrip bandpass filter](image)

In Figure 11, the return loss ($S_{11}$) reached its maximum of -19 dB at around 2.25 GHz, which is the same frequency value with that of the $S_{21}$. 
Figure 11. The measured $S_{11}$ of the parallel coupled line microstrip bandpass filter

Figure 12 shows the measured result of the MAF system, with the measured frequency ranged from 1.9 GHz to 2.5 GHz. The measure was done by picking the amplitude values of the receiving signal over the measured frequency range with the frequency step of 2.5 MHz, corresponds to 240 points over the whole frequency span.

Figure 12. The measured $S_{21}$ of the whole Microwave Active Filter

In Figure 12, the operation frequency range is between 2 GHz and 2.4 GHz, which corresponds to a bandwidth of 400 MHz. The highest gain value is 16.1 dB at around 2.36 GHz and the gain values around the center frequency of the bandpass filter are approximately 14 dB. The actual peaked gain without respect to the cables and connector attenuations is about 20 dB. The highest gain value is 16.1 dB at around 2.36 GHz and the gain values around the center frequency of the bandpass filter are approximately 14 dB. The actual peaked gain without respect to the cables and connector attenuations is about 20 dB. The fluctuation of the gain range is roundly 5 dB, however, it can be compensated by the S-band receiver’s automatic gain control (AGC). A noticeable trait of the above gain diagram is that the values fall rapidly outside the desired range, for details, from 10 dB at 1.98 GHz to -20 dB at 1.95 GHz and from 10 dB at 2.43 GHz to -20 dB at 2.45 GHz. This is a valuable characteristic of our MAF. However, the most important point, which is also the main goal of our design is that the MAF has the ability of flexibly tuning the frequency over the entire operational frequency bandwidth. As can be seen in Figure 12, the $S_{21}$ of the 2–2.4 GHz range considerably fluctuates from 11 dB to 16 dB. However, when dividing this to 10 internal frequency slots of 40 MHz we have flattened sub-ranges, in which, the vibrations of $S_{21}$ is less than 1 dB. These local frequency spans allow the front-end receiver to perform multi-frequency receiving in the whole desired range. This can be done by integrating the receiver to a frequency switching circuit. Furthermore, the frequency
slots can be further increased when combining the MAF with a phase-locked loop (PLL) frequency synthesizer unit in order to do the flexible stepped tuning [17]. It provides undeniable advantages to the multi-frequency satellite communication.

5. Conclusion
This paper introduced about a micro wave active filter consists of a coupled line microstrip bandpass filter and a wideband low noise amplifier. The simulated and measured results are being presented and it proved good agreement between simulation and practice. The MAF is successfully designed and operated at S-band, and it can be applied to nanosatellite’s receiver fronts-end at both space and ground segments. The operation range of the proposed MAF is 2-2.4 GHz and the highest gain value is around 20 dB. The MAF allows good stepped frequency tuning at S-band and it proves considerable benefits in comparison to general passive filter systems, such as: Provides considerable high gain signal at the operating band, better frequency response and noise compensating for the filter, and still compact enough to integrate to the nanosatellite’s receivers. Based on the requirement of the communication satellite missions, the flatness and frequency response of the operation band can be further improved when increasing the order of the filter, this can be used for applications that required smoother frequency tuning.
