We study suspensions of semiflexible colloidal rods and biopolymers using an Onsager-type second-virial functional for a segmented-chain model. For mixtures of thin and thick fd virus particles, we calculate full phase diagrams, finding quantitative agreement with experimental observations. We show that flexibility, which renders the rods effectively shorter and fatter depending on the state point, is crucial to understand the topologies of the phase diagrams. We also calculate the stretching of wormlike micelles in a host fd virus suspension, finding agreement with experiments.

Rodlike particles are capable of forming a great variety of liquid-crystalline phases [1], and have been widely explored experimentally and theoretically [2]. Today, a prominent role is being played by aqueous suspensions of fd virus particles, which are charged, semiflexible, Brownian needles with a length-to-diameter ratio exceeding 100, exhibiting isotropic (I), cholesteric nematic (N), smectic, columnar, and crystalline phases upon increasing the concentration [3–5]. Moreover, wild-type fd virus particles have been bioengineered to have, for instance, a polyethylene-glycol (PEG) coating, such that mixtures of thin and thick rods with diameter ratios d varying from 1.1 to 3.7 could be studied experimentally [6]. The resulting phase diagrams are extremely rich, even in the regime where only I and N phases are relevant. The observations not only include I-N coexistence with strong fractionation effects but also, for d ≥ 3, two-phase N-N and three-phase I-N-N coexistence with phase diagram topologies that strongly depend on d. Given the needlelike shape of the fd virus particles, and the relative structural simplicity of I and N phases, one would expect these phase diagrams to be well understood, e.g., resembling those of theoretical predictions based on Onsager’s second-virial theory for thin-thick mixtures of rigid rods [7]. However, these systems turn out to be surprisingly poorly understood. For instance, the experiments show N-N demixing with a low-density (lower) critical point that shifts to lower densities with increasing d [6], while the theory predicts the exact opposite: a high-density (upper) N-N critical point and N-N demixing that extends to higher densities with increasing d [7,8]. Moreover, the experiments show N-N demixing at diameter ratios as low as d ≥ 2–3 while rigid-rod models predict d ≥ 4–5 [6,7]. In this Letter we will show that the key to a real understanding of these systems is flexibility, which renders the needles effectively shorter and fatter depending on the state point [9,10]. In addition, our model and theory can also quantify the observed stretching of guest biopolymers in host suspensions of fd virus particles [11].

One-component systems of semiflexible rods have been studied using numerous methods, and it is known that only a slight flexibility is enough to shift the I-N transition to significantly higher concentrations [12–16]. We follow the segmented-chain model introduced by Wessels and Mulder [16], in which (i) flexibility is incorporated by introducing a bending potential between the chain segments and (ii) excluded volume is taken into account at the segment level. This approach reproduces (in the appropriate limits) the results of Ref. [12], with the advantage of only having to deal with a discrete number of degrees of freedom. Here, we generalize this model to two-component systems and map out, for the first time, the full phase behavior beyond stability analysis. Moreover, we calculate the effective particle shape, which turns out to be strongly state-point dependent.

We consider a suspension of Ni semiflexible rods of species i = 1, 2 with contour lengths Li, in a volume V at temperature T. Following Ref. [16] we model a rod of species i as a chain of Mi rodlike segments of length li = Li/Mi and diameter Di ≪ li. Denoting the orientation of the mth segment by a unit vector ωm (with 1 ≤ m ≤ Mi), we write the bending energy of a chain of species i with orientation Ω = {ω1, ..., ωMi} as

\[ U_i(Ω) = \sum_{m=1}^{M_i-1} u_i(\omega_m, \omega_{m+1}) = -\frac{P_i}{l_i} \sum_{m=1}^{M_i-1} \omega_m \cdot \omega_{m+1}, \]  

where stiffness is described in terms of the persistence length Pi [16]. Throughout we use thermal energy units by setting kBT = 1. The state of the suspension is characterized by the orientation distribution functions (ODFs) fi(Ω), which satisfy the normalization condition \( \int dΩ f_i(Ω) = 1 \), where \( dΩ = \prod_{m=1}^{M_i} dω_m \). Denoting the total number of rods by N = Ni + N2, the density by \( \rho = N/V \), and the mole fraction of species i by \( x_i = N_i/N \), we generalize the variational free energy functional in Ref. [16] to \( F[f_1, f_2] \) to describe binary mixtures within an Onsager-like second-virial approximation as

0031-9007/11/106(20)/208302(4) 208302-1 © 2011 American Physical Society
The first line of Eq. (2) represents the translational and the mixing ideal-gas contributions (with $B = \frac{\pi}{4} D_1 L_1^2$, a constant), the second line denotes the orientation entropy and bending energy, and the third line the excluded volume interactions, which can be considered at the segment level with $K_{ij}(\Omega, \Omega') = \sum_{m=1}^{M_i} \sum_{m'=1}^{M_{i'}} k_{ij}(\omega_m, \omega_{m'})$. For $M_i = 1$ and $U_i = 0$, Eq. (2) reduces to the Onsager functional for binary mixtures of rigid rods [7,17]. From hereon, we simply summarize our method and direct those interested in the complete outline to Ref. [8]. At a given thermodynamic state point, the equilibrium ODFs minimize $F$ and therefore satisfy

$$f_i(\Omega) = \frac{\exp[-U_i(\Omega) - V_i(\Omega)]}{Q_i},$$  

$$V_i(\Omega) = \rho \sum_{j=1}^{2} x_j \int K_{ij}(\Omega, \Omega') f_j(\Omega') d\Omega',$$

where $V_i(\Omega)$ can be seen as a self-consistent field acting on all segments of a chain, and $Q_i$ is a partition functionlike normalization factor [16]. Explicitly solving Eqs. (3) and (4) for state points of interest would be prohibitively expensive computationally due to the high-dimensional angular $\Omega$ grids that would be required in the case when $M_i \gg 1$. Instead, we formally evaluate the functional $F$ of Eq. (2) in its minimum by inserting the solutions $f_i$ of Eqs. (3) and (4) to find the equilibrium free energy

$$\frac{F_{\text{eq}}}{N} = \ln(B \rho) - 1 + \frac{x_1}{Q_1} x_1 \ln x_1 + x_2 \ln x_2 - \frac{1}{2} \rho \sum_{i,j} x_i x_j \sum_{m=1}^{M_i} \sum_{m'=1}^{M_{i'}} k_{ij}(\omega, \omega') f_{i,m}(\omega) f_{j,m'}(\omega') d\omega d\omega',$$

where $f_{i,m}(\omega)$ is the ODF of the $m$th segment of a chain of species $i$ given by $f_{i,m}(\omega) = \int f_i(\Omega) \delta(\omega - \omega_m) d\Omega$. Equation (5) implies that the thermodynamics does not require the full solutions $f_i(\Omega)$ but only the $M_i$ single-segment ODFs $f_{i,m}(\omega)$ and the normalization factors $Q_i$. The calculation of these is given in Ref. [8]. With the ODFs, and hence $F_{\text{eq}}$, known, all thermodynamic properties such as osmotic pressure $\Pi$ and phase diagrams follow [7].

We have calculated the phase diagrams for mixtures of bare $fd$ particles (species 1, thin) and PEG-coated ones (species 2, thick), with equal contour and persistence lengths, $L_1 = L_2 = 0.88 \mu m$ and $P_1 = P_2 = 2.2 \mu m$ [6]. The bare $fd$ diameter is fixed to $D_1 = 6.6$ nm, and following the experiments of Ref. [6] we consider several diameter ratios $d = D_2/D_1$ to describe varying thicknesses of the PEG coating. We use sufficient segments per virus particle such that we are in the continuum limit for all state points of interest [8]. In Fig. 1 we show, for several $d$, the resulting phase diagrams in the $(\rho_1, \rho_2, B)$ representation, including the scaled [8] experimental data from Ref. [6]. For all $d$ we find isotropic-nematic ($I-N$) coexistence, with the tie-lines indicating, for increasing $d$, an increasing fractionation of the thinner and thicker rods preferentially into the $I$ and $N$ phase, respectively.

In agreement with the experiments of Ref. [6], we find no $N-N$ coexistence in the density regime of interest for the smallest diameter ratio $d = 1.2$ [Fig. 1(a)]. For increasing $d$ an $N-N$ demixing regime appears in the density regime of interest, with a lower critical point as shown for $d = 3.1$ in Fig. 1(b); in the experiments of Ref. [6] such a phase diagram was found for $d \approx 2.9$. Slightly increasing the PEG layer thickness to $d = 3.11$ reveals an $I-N-N$ triple

![FIG. 1 (color online). Phase diagrams (see text) for mixtures of bare (thin) $fd$ virus particles (species 1) and PEG-coated (thick) ones (species 2), with diameter ratios (a) $d = 1.2$, (b) 3.1, (c) 3.11, (d) 3.5, (e) 6. The lighter colored areas indicate the two-phase regions with tie-lines connecting coexisting state points; triangles denote $I-N-N$ and $I-N$ triple points. Experimental results from Ref. [6] are shown by circles ($I-N$) and squares ($N-N$) for (a) $d = 1.1$, (b) 2.9, and (d) 3. (f) Topology of the phase diagram (two- and three-phase coexistence) of binary mixtures of (modified) $fd$ virus particles as a function of their diameter ratio $d$ and persistence length $P$.](208302-2)
point and an associated $N$-$N$ demixing regime with an upper critical point emerging out of the $I$-$N$ coexistence regime [Fig. 1(c)]. This $N$-$N$ upper critical point has not been reported experimentally, perhaps because it only exists in a small regime of diameter ratios; for $d = 3.125$ the upper and lower $N$-$N$ points have merged to form a single neck-shaped $N$-$N$ regime that is separated from the $I$-$N$ coexistence regime by an $I$-$N$-$N$ triple point, with the $I$ and one $N$ phase rich in bare $fd$ particles and the other $N$ phase rich in PEG-coated $fd$ particles [Fig. 1(d)] shows an example of this behavior for $d = 3.55$. Interestingly, such neck-shaped phase diagrams have also been reported in Ref. [6] for diameter ratios $d \geq 3$. For $d = 6$, Fig. 1(e) shows an $I$-$I$-$N$ triple point and $I$-$I$ coexistence, as found also for thin-thick mixtures of rigid rods with diameter ratios exceeding $d \approx 8$ [7]. We find that this behavior is present for $d \geq 4.5$. We also compare our results in Fig. 1 to experimental data from Ref. [6], using a $d$ value that gives the best fit. At low $d$ we find excellent agreement, although we must use a $d$ value of 1.2 (compared to the experimental value of 1.1). For larger $d$, we tend to slightly overestimate the size of the $I$-$N$ coexistence region. However, our results are qualitatively much closer to the experimental data than those obtained for rigid rods (see also Ref. [8]).

Motivated by recent progress in the bioengineering of $fd$ virus particles [18], which may allow for tuning their flexibility, we have also calculated phase diagrams for a large variety of diameter ratios and persistence lengths $P_1 = P_2 = P$. Figure 1(f) summarizes our findings by dividing the $(d, P)$ plane into regions with phase diagrams featuring only an $I$-$N$ transition (for stiff rods and small $d$) all the way to complex phase diagrams with $I$-$N$, $I$-$I$, $N$-$N$ phase coexistence and $I$-$I$-$N$ and $I$-$N$-$N$ triple points (for flexible rods and large $d$). Clearly, increasing $d$ and decreasing $P$ have similar effects on the phase diagram, and hence increasing the flexibility is expected to considerably enhance the complexity of the phase diagrams.

In order for a model system of rigid rods to begin to capture the phase behavior of binary $fd$ virus systems, one must use a system of much shorter, thicker rods, with $L/D \approx 7$ for the PEG-coated $fd$ virus [6], much lower than the true values of 20–110. The inference is that long semiflexible rods exhibit the same phase behavior as short rigid rods [9,10]. Our model enables us to define an effective shape, whereby we map the excluded volume of the semiflexible rods onto that of rigid rods. We define the mean square effective length $L_{e,i}$ as

$$L_{e,i}^2 = \sum_{m=1}^{M} \sum_{m'=1}^{M} \int (\omega \cdot \omega') f_{i,m,m'}(\omega, \omega') d\omega d\omega', \quad (6)$$

where $f_{i,m,m'}(\omega, \omega')$ is the pair orientation distribution function (PDF) (calculated in Ref. [8]). We use the PDFs to calculate $L_{e,i}$, and, from this, the effective diameter $D_{e,i}$ required for rigid rods of length $L_{e,i}$ to have the same excluded volume as flexible rods of length $L_i$.

Figure 2(a) shows the effective shape $L_{e,i}/D_{e,i}$ for a mixture of thick-thin $fd$ virus particles with $d = 3$, throughout the phase diagram [the route we follow is shown in Fig. 2(b), where we use the $x_2$-$II$ representation for clarity]. It is immediately apparent that throughout the phase diagram, while the rods always behave as shorter, thicker rods, the effective shape varies considerably. In the isotropic phase, we find for both species $L_{e,i}/D_{e,i}$ to be about 20% of $L_i/D_i$. This corresponds to $L_{e,i}/D_{e,i} = 8.5$ for the thick rods, close to the $L_i/D_i \leq 7$ required for rigid-rod systems to capture the phase behavior of these binary systems [6]. For the nematic phase, however, $L_{e,i}/D_{e,i}$ jumps to over 50% of $L_i/D_i$, and increases considerably as $II$ is increased. Interestingly, the thick rods stretch out more than the thin rods, with the rods now effectively differing in both diameter and length. We conclude that a fixed effective shape does not capture the essential physics of these suspensions; the state-point dependent stretching of the flexible rods is a key feature.

Finally, we present results for the effective length of semiflexible polymers dissolved in an $fd$ virus suspension. A range of polymers which undergo a coil-rod transition, stretching out over the $I$-$N$ transition of the host $fd$ virus, has been studied experimentally [11]. Here, we examine wormlike micelles, which have constant $P = 0.5 \mu$m, $\bar{D} = 14$ nm and variable $L = 5$–50 $\mu$m. The concentration of the polymers is sufficiently low that they can be treated as a single particle in a bulk $fd$ virus suspension, and we study the behavior of the polymer $L_e$ over the $I$-$N$ phase transition of the $fd$ virus (found at $IIB = 29.54$). The results are shown in Fig. 3(a). For the shortest polymers studied, we see a considerable jump in $L_e$, from $L_e \approx 0.26L$ to $\approx 0.61L$, corresponding to a coil-rod transition. For longer polymers, the jump in $L_e$ becomes smaller, and the longest ones only become truly rodlike well into the nematic phase of the $fd$ virus. It is interesting to note that in the isotropic phase, for all cases, $L_e$ appears to remain essentially constant.

In the isotropic $fd$ virus phase, the polymer may be considered along the lines of the Kratky-Porod wormlike chain model [19], generalized to account for excluded
In conclusion, we have developed a model for binary mixtures of semiflexible rods and applied it to binary \( fd \) virus mixtures. The addition of flexibility in our model gives results that are quantitatively much closer to experimental data than those obtained using rigid rods [6]. The key reason appears to lie in the effective shape of the rods, which changes throughout the phase diagrams and can effectively render them a mixture of rods of differing diameter and length, indicating that any static-shaped rigid-rod model will miss some of the essential physics. In addition, we have studied the stretching of semiflexible polymers in an \( fd \) virus solvent. We find that sufficiently short polymers stretch out considerably over the \( I-N \) transition of the host solvent, while for the longer ones some stretching is observed, but the effect is much less pronounced. Changing the stiffness of the host \( fd \) virus can greatly increase the stretching effect. We hope that our findings will stimulate further experimental explorations, and believe that extensions of the theory to, e.g., inhomogeneous states and nonequilibrium phenomena are within reach of the present model.
