Star clusterings in the Carina complex: 
UBVRI photometry of Bochum 9, 10 and 11

ABSTRACT
We report on the first UBVRI CCD photometry of three poorly known star clusterings in the region of η Carinae: Bochum 9, Bochum 10 and Bochum 11. We found that they are young, rather poor and loose open clusters.

We argue that Bochum 9 is probably a small and loose open cluster with about 30 probable members having E(B − V) = 0.63±0.08, located 4.6 kpc far from the Sun, beyond the Carina spiral arm.

Similarly, Bochum 10 is a sparse aggregate with 14 probable members having E(B − V) = 0.47±0.05 and at a distance of 2.7 kpc from the Sun.

Finally, Bochum 11 is a less than 4 × 10^6 yrs old cluster for which we identify 24 members. It has a reddening E(B − V) = 0.58±0.05, and lies between Bochum 10 and 9, at 3.5 kpc from the Sun. We propose that in the field of the cluster some stars might be pre Main Sequence (MS) candidates.

Key words: Open clusters and associations–Individual: Bochum 9; Open clusters and associations–Individual: Bochum 10; Open clusters and associations–Individual: Bochum 11;

1 INTRODUCTION
Feinstein (1995) suggests that there are 14 known or suspected open star clusters probably related to the Carina spiral feature. Most of them are actually very well known. Nonetheless some remain very poorly studied, and our knowledge often does not extend beyond the simple identification. As a consequence the real nature of some of these star clusterings and their belonging to the Carinae complex are not well established.

The region of η Carinae on the other hand is since long time recognized as an ideal laboratory to study the formation of star clusters by obtaining precise photometry and age estimates (Massey and Johnson 1993). Having this in mind, we have undertaken a photometric survey aimed at obtaining homogeneous high quality CCD data for all the known star clusterings in this region. We already reported about NGC 3324 and Loden 165 (Carraro et al 2001), showing that Loden 165 does probably not belong to the Carina complex.

Here we report on three poorly studied objects: Bochum 9, Bochum 10 and Bochum 11, identified in the seventies by Moffat & Vogt (1975). Only photoelectric photometry is available for these objects; in particular Bochum 9 deserves special attention since it is not clear whether it is a cluster or not. The other two clusters are young objects, with some evidence of a pre MS population (Fitzgerald & Mehta 1987). Their basic parameters are given in Table 1.

The plan of the paper is as follows. In Section 2 we describe the data acquisition and reduction, while Sections 3 to 5 are dedicated to Bochum 9, Bochum 10 and Bochum 11, respectively. Finally Section 6 summarizes our results, and in the Appendix we provide some additional details on the data reduction and photometric errors.

2 DATA ACQUISITION AND REDUCTION

Observations were conducted at La Silla on April 13-16, 1996, using the imaging Camera (equipped with a TK coated 512 × 512 pixels CCD #33) mounted at the Cassegrain focus of the 0.92m ESO–Dutch telescope. All nights were photometric with a seeing ranging from 1′′ to 2′′. The scale on the chip is 0′′.44 and the array covers about 3′.3 × 3′.3 on the sky. Due to the projected diameter of the objects and the relatively small field of view, it was necessary to observe four fields for the same object. To allow for a proper photometric calibration and to assess the night quality, the standard fields RU149, PG1323, PG1657, SA 109 and SA 110 (Landolt 1992) were monitored each night. Finally, a series of flat–field frames on the twilight sky were taken. The scientific exposures have been flat–field and bias corrected by means of standard routines within IRAF†. Further reductions were performed using the DAOPHOT package (Stetson 1991) in the IRAF environment.

The instrumental magnitudes have been transformed into standard Bessel UBVRI magnitudes using fitting coefficients derived from observations of the standard field stars from Landolt (1992), after including exposure time normalization and airmass correction. Aperture corrections have also been applied. The observations log-book for the three clusters is presented in Table 2, whereas additional details of the photometric reduction and error analysis are provided in the Appendix.

3 BOCHUM 9

Bochum 9 appears as a sparse group of 7 blue luminous stars westwards of η Carinae. This star clustering was identified and studied by Moffat & Vogt (1975) who provided photometric photometry for 22 stars. They concluded that 12 of them are O and B type stars, but the sample seems not to show any sequence, and this raises some doubts about the

† IRAF is distributed by the National Optical Astronomy Observatories, which is operated by the Association of Universities for Research in Astronomy, Inc., under contract to the National Science Foundation.

Figure 2. CMDs for all stars in the region of Bochum 9. The dashed line indicates the limiting magnitude reached by previous investigations.

Figure 3. Two colors diagram for all stars in the region of Bochum 9 having V ≤ 16.5. The arrow indicates the reddening vector. The solid line is the empirical Schmidt-Kaler (1982) ZAMS. Open squares indicate stars having E(B − V) = 0.63 ± 0.08, and the dashed line crossing these stars is an empirical ZAMS shifted by E(B − V) = 0.63. Most of the other stars lie along an empirical ZAMS (long dashed line) shifted by E(B − V) = 0.18. See tex for additional details.
Figure 4. CMDs for all the stars in the region of Bochum 9 having $V \leq 16.5$ and sharing the reddening $E(B-V) = 0.63 \pm 0.08$. The empirical ZAMS from Schmidt-Kaler (1982) is shown as a solid line and as been shifted according to the reddening and distance modulus. The dashed line represents the same ZAMS 0.75 mag brighter, which defines the locus of unresolved binaries. See the text for more details.

Figure 5. The projected spatial distribution of the candidate cluster members in the field of Bochum 9. The size of the circles is proportional to the magnitude of the stars. The field is about $6' \times 6'$. 

Figure 6. Vector point diagram for Tycho 2 stars in the field of Bochum 9. Proper motions are expressed in mas/yr, and crosses, where available, indicate the uncertainties.

3.1 Color-color and color-magnitude diagrams

The position of all the stars brighter than $V = 16.5$ in the color-color diagram is shown in Fig. 3. The solid line is the un-reddened Schmidt-Kaler (1982) sequence. There seems to be two distinct populations. The bulk of the stars are indicated with filled squares, and are fitted by an empirical ZAMS (long dashed line) shifted by $E(B-V) = 0.18$. This sequence is probably due to stars in the Galactic disk located between us and the Carina spiral arm. There is however another group of stars, plotted with open squares, sharing a common reddening $E(B-V) = 0.63 \pm 0.08$. 

© 2001 RAS, MNRAS 000, 1–12
They are 48 stars. The sequence (dashed line) crossing these stars is the same empirical ZAMS as above, but shifted by $E(B-V) = 0.63$.

We shall refer to the more reddened sequence as Bochum 9 candidate members. In order to better understand the nature of Bochum 9 we plotted the cluster candidate members in the color-magnitude diagrams shown in Fig. 4. The selected stars define a tight sequence in the $V$ vs $(B-V)$ plane (Fig. 4, left panel), where we super-imposed an empirical ZAMS shifted by $E(B-V) = 0.63$ and by the apparent distance modulus $(m-M) = 15.3$. In the right panel we present the $V$ vs $(U_B)$ CMD for the same group of stars. It seems that they still follow a sequence, although somewhat scattered below $V = 15.3$. In this panel the ZAMS has been shifted by $E(U-B) = 0.44$ and by the apparent distance modulus $(m-M) = 15.3$. The appearance of these CMDs suggests that of Bochum 9 is a probable very young loose open cluster located about 4.6 kpc far from the Sun, beyond the Carina spiral arm. To better identify cluster members we assumed that some of the stars in Fig. 4 might be binaries. Unresolved binaries populate a sequence 0.75 mag brighter than the single stars ZAMS, offering us the possibility to define the width of the MS. The binaries sequence has been drawn in Fig 4 as a dashed line. As a consequence, if we consider as non member all the stars lying out of the region defined by the two ZAMS, the number of candidate members turns out to be 29.

The projected spatial distribution of the candidate members in shown in Fig. 5. The stars do not show any cluster like distribution, raising some doubts on the cluster nature of Bochum 9.

### 3.2 Astrometric data

For 7 of the most luminous stars we have at disposal the absolute proper motions provided by Tycho 2 (Heg E. et al. 2000), and they are listed in Table 3. First of all, we want to stress that the uncertainties in the measurements (due to the fairly large distance) cannot help too much, to draw any firm conclusions. Anyhow, while they appear broadly consistent in $\mu_\delta$ (except for GSC08957-0270), they seem to form two sub-groups in $\mu_\alpha$. HD 305364 shares the same $\mu_\alpha\delta$ of HD 305383, HD 92025 and maybe HD 305366, while HD 305368 has basically the same $\mu_\alpha\delta$ of HD 305770. The star GSC08957-02702 probably is an isolated case.

The available data do not allow us to decide unambiguously about the nature of Bochum 9. It is clear that the Galactic disk component is rather strong in this direction (Vallenari et al 2000). Anyhow, we believe that we are probably facing a young loose open cluster about 4.6 kpc far from the Sun, at odds with previous suggestions by Moffat & Vogt (1975). We emphasize that proper motions provide only a weak suggestion, and that radial velocities for the brightest stars or a dedicated relative proper motions survey are needed to decide about the real nature of Bochum 9.

The position in the CMDs (see Fig. 4) of some stars below $V = 14.5$ deserves a final consideration. The most plausible explanation for the scatter in this region is that these stars can be field stars. However, there is the possibility that some of them might be pre MS stars, an hypothesis which demands further investigations by $H_\alpha$ equivalent width measurements or infrared photometry (see for instance Vallenari et al 1999 and the discussion for Bochum 11 in Sec. 5.2).

### 4 BOCHUM 10

Bochum 10 is a loose open cluster located north-west of $\eta$ Carinae, and surrounded by a diffuse nebulosity (Smith et al 2000). We therefore expect to find signatures of variable extinction across the cluster. Bochum 10 was firstly reported by Moffat & Vogt (1975) who obtained $UBV$ photoelectric photometry for 17 stars, and found 12 possible members. Later Feinstein (1981) obtained photoelectric $UBVR$ photometry for 39 stars down to $V = 13$, recognizing 15 members. Finally, Bochum 10 has been studied by Fitzgerald & Mehta (1987) who provide photoelectric $UBV$ photometry of about twenty stars down to $V = 13.5$. They suggest that the cluster is rather sparse and includes O and B stars only. No members are suggested to exist below $V = 13.5$.

While all these studies give the same estimate of the reddening, being $E(B-V) \approx 0.35$, there are some discrepancies in the distance modulus, which ranges from $(m-M)_o = 12.03$ to 12.80. According to Moffat & Vogt (1975) the cluster is 2.56 kpc far from the Sun, whereas for Feinstein (1981) is 3.6 kpc distant and for Fitzgerald & Mehta (1987) about 2.8 kpc. The precise distance of Bochum 10 is crucial to assess its membership to the Carina complex. As for the age, there is some agreement in the literature, being the cluster as old as $7 \times 10^6$ yrs.

For this object we obtained $UBVRI$ photometry for about 600 stars down to $V = 20$. The comparison of our...

Our field (see Fig. 6) comprises the region defined by the 7 brightest stars mentioned by Moffat & Vogt (1975), but it is much smaller than the fields studied by Feinstein (1981) and Fitzgerald & Mehta (1987). By inspecting a DSS map it appears however difficult to define the cluster center, since there are several bright stars evenly distributed within a radius of 20′ from the assumed cluster center which seem to form separated clumps. Anyhow, if we are really sampling the cluster core, our photometry supersedes all previous studies and we can obtain improved estimates of the cluster fundamental parameters.

4.1 Color-magnitude diagrams

The CMDs for all detected stars in the field of Bochum 10 are shown in Fig. 8, where the dashed line indicates the limiting magnitude of previous investigations. The CMD looks very similar to that of Bochum 9, shown in Fig. 2. Since the field is much smaller, there are less stars, but their distribution is practically identical, with a thin MS extending from \(V = 9\) to \(V = 20\).

The contribution of field stars is negligible up to \(V = 14.0\). At fainter magnitudes, the MS is dominated by the Galactic disk population. As in the case of Bochum 9, there are some indications of Galactic disk RG stars, at least looking at the scarcely populated vertical sequence which departs from the MS at \(V\) about 20.

The most prominent difference with Bochum 9 is the presence of a clump of stars in the bright end of the MS.

Figure 8. CMDs for all the stars in the region of Bochum 10. The dashed line defines the limit of previous photometries.

4.2 Two color diagram

All the stars having \(UBV\) photometry have been plotted in the two color diagram in Fig. 9. Most of them exhibit basically no reddening, like the bulk of stars in Bochum 9. However the clump of stars at \((B-V) = 0.1\) and \((U-B) = -0.7\) has a larger reddening \(E(B-V) = 0.47\), and is identified by an empirical ZAMS shifted by this amount (dotted line). Since these stars have a common extinction, which is significantly larger than that undergone by the bulk of the stars, it is reasonable to see whether they define a distinct sequence in the color magnitude diagram.
Star clusterings in the Carina complex: UBVRI photometry of Bochum 9, 10 and 11

Figure 9. Two colors diagram for all the stars in the region of Bochum 10. The arrow indicates the reddening vector. The solid line is the empirical Schmidt-Kaler (1982) ZAMS, whereas the dotted line is the same ZAMS, but shifted by E(B − V) = 0.47. Filled circles indicate candidate members.

Figure 10. Reddening corrected CMDs for the candidate member stars in the region of Bochum 10. The solid line is the empirical ZAMS from Schmidt-Kaler (1982), whereas the dashed line is the same ZAMS, but shifted by 0.75 mag to define the locus of unresolved binaries. Open circles indicate probable non members. See text for details.

Table 6. Photometry and astrometry of the brightest stars in the field of Bochum 11. Proper motions are taken from Tycho 2 and are expressed in mas/yr.

| ID     | Name      | V    | (B − V)(U − B) | μασ  | σμα | μδ | σμδ | Type |
|--------|-----------|------|-----------------|------|-----|----|-----|------|
| 1      | HD 93632  | 8.326| 0.231           | -0.762| -129.80| 2.70| 112.00| O      |
| 2      | HD 93576  | 9.661| 0.163           | -0.729| -55.00| -3.00|       |        |
| 3      | HD 305612 | 10.288| 0.270          | -0.729| -5.50  | -3.00|       | B      |
| 4      | HD 93632B | 10.489| 0.122           | -0.711| -7.90  | 3.30| 5.80  | B2V    |
| 5      |           |      |                 | 10.582| 0.303 | -0.600|       |        |
| 6      | CPD 59270 | 10.841| 0.347           | -0.596|       |     |       |        |
| 7      |           |      |                 | 11.321| 0.080 | -0.702| -1.40| 5.60  | B      |
| 8      |           |      |                 | 11.819| 0.372 | -0.447|       |        |

For this purpose we selected all the stars having 0.42 ≤ E(B − V) ≤ 0.52 (18 stars in total). These are plotted in Fig. 10, and seem to actually define a clear sequence. There are 6 stars which lie off the MS, and they are plotted with open circles. The ZAMS has been over-imposed by adopting (m − M)V = 12.20, which implies a distance of 2.7 kpc from the Sun. The dashed line in Fig. 10 represents the same ZAMS 0.75 mag brighter, and it defines the ZAMS of unresolved binaries. Accordingly the two stars at V0 ≈ 12.3, (B − V)0 ≈ −0.8 may be binaries.

We looked for the relative position of these stars within the cluster, and found that, with the exception of the two binaries, they lie in the outskirts of the area we covered. Therefore we suggest that these stars do not probably belong to Bochum 10.

4.3 Astrometric data

Tycho 2 provided measurements of proper motions for 17 stars in the field of Bochum 10. They are listed in Table 6, and plotted in the vector point diagram in Fig. 11. Also in this case we stress that the uncertainties in the proper motions are large. Nevertheless, the distribution of the points in Fig. 11 is conducive to argue that two separate clumps with a large spread seem to exist, while one object (HD 93114) clearly deviates from the bulk.

If these clumps are real, we are most likely looking at a group of objects which do not share the same motion properties. Interestingly Feinstein (1981) on a purely photometric basis attributed membership to stars having discrepant motion (see Fig 11). Finally, by closely inspecting the spatial distribution of these stars in the sky (see Feinstein 1981, Fig. 1.) it is possible to see how presumed members do not distribute in the central region the cluster, but members and non-members mix together.

In conclusion, the results we obtained for Bochum 10 are the following. As in the case of Bochum 9, there are indications that we are not looking at a really bounded open cluster, but simply at a loose group of bright stars embedded in a rich Galactic Disk field.

We found 14 probable members, less than Fitzgerald & Metha (1987), probably because we have sampled a region too small to be really representative. The cluster seems to be quite young, with no stars in the act of leaving the MS.

In order to better clarify the nature of Bochum 10, we suggest further investigations in two directions: a radial velocity survey for the brightest stars and a larger area for the photometric coverage.

5 BOCHUM 11

Bochum 11 is a compact very young group of stars around the double star HD 93962 (see Fig. A1). The diffuse nebulosity (see Fig. 12) which surrounds Bochum 11 is possibly what remains of the cloud from which the cluster was born. It was firstly investigated by Moffat & Vogt (1975), who provided UBV photoelectric photometry for 8 probable members. Soon after Forte (1976) obtained UBV photoelectric photometry for two stars already studied by Moffat & Vogt (1975). Interestingly, Moffat & Vogt (1975) pointed out that the cluster suffers from differential reddening, being $E(B-V) = 0.54 \pm 0.13$. Moreover they suggested that the stars fainter than $V = 12$ may be pre MS stars in contraction phase.

Finally, additional photoelectric photometry has been carried out by Fitzgerald & Mehta (1987), who added 9 more stars. By increasing to 15 the number of members, they confirmed that Bochum 11 is very young and pre MS stars are possibly present below $V = 12$.

A comparison with the work of Fitzgerald & Mehta (1987) for 9 stars in common (see the details in Table 7), yields the following results:

\[
V_{PC} - V_{FM} = -0.044 \pm 0.042
\]

\[
(B-V)_{PC} - (B-V)_{FM} = -0.055 \pm 0.037
\]

\[
(U-B)_{PC} - (U-B)_{FM} = -0.001 \pm 0.029
\]

where PC refers to the present study, FM to Fitzgerald & Mehta (1987).

Our study covers a region of $3' \times 6'$ (see Fig. 12) and we obtained CCD UBVRI photometry for about 780 stars down to $V = 21$ (see Fig. 13), superseding all previous investigations. The CMD in Fig. 12 look quite similar to those...
5.1 Cluster reddening

We isolated Bochum 11 possible members on the basis of the position in the two colors diagram (see Fig. 14) and in the map in Fig. A1. By considering the stars distribution as projected onto the sky (Fig. A1), we selected four regions, namely a circle centered in HD 93632 with a radius of 50′′ (upper left panel in Fig. 13), two coronae defined by 50′′ ≤ r ≤ 110′′ (upper right panel) and 110′′ ≤ r ≤ 150′′ (lower left panel), and finally the region outside the last corona, defined by r ≥ 150′′.

In all these figures, the empirical Schmidt-Kaler (1982) ZAMS is plotted as a solid line, whereas the same ZAMS, shifted by E(B − V) = 0.58, is drawn as a dotted line. The central region seems indeed to be constituted by a group of 5-10 stars sharing the same reddening E(B − V) = 0.58, whereas the majority of stars lying outside the cluster core have basically no reddening, like in the case of most of Bochum 9 and 10 stars. It is reasonable to conclude that these are field stars.

We have indicated with filled circles candidate cluster members on the basis of common reddening. Noticeably, we find probable cluster members also in the outer rings. In total, the candidate members are 30. By considering all the probable members, the reddening turns out to be E(B − V) = 0.58 ± 0.05.

This value is in good agreement with previous estimates. In fact Moffat & Vogt (1975) found E(B − V) = 0.54 ± 0.13, whereas Fitzgerald & Mehta (1987) derived E(B − V) = 0.588 ± 0.032.

5.2 Age and distance

Age and distance have been inferred by fitting the reddening corrected CMDs with solar metallicity isochrones (Girardi et al 2000). This is shown in Fig. 15, where we plotted all
the candidate members according to reddening. Some stars which lie apart from the MS are indicated with open circles and considered probable non members reducing at 24 the number of cluster members.

In this figure the dashed line is an isochrone for the age of $8 \times 10^6$ yrs and the dotted one an isochrone for the age of $4 \times 10^6$ yrs, both shifted by $(m - M)_0 = 12.70$, in fair agreement with previous estimates. In fact Moffat & Vogt (1975) suggested $(m - M)_0 = 12.80$, whereas Fitzgerald & Mehta (1987) derived $(m - M)_0 = 12.70$. The distance from the Sun is estimated to be 3.5 kpc and therefore Bochum 11 is lies between than Bochum 10 and 9. The comparison with isochrones suggests that Bochum 11 is a very young cluster with an age less than $4 \times 10^6$ yrs.

The possibility that pre-MS stars are present in Bochum 11 was already suggested by Fitzgerald & Mehta (1987), who argued that these stars have to be fainter than $V = 12$. The position of the stars in Fig. 15 below $V = 12$ seems to support this hypothesis, which demands further investigations by $H_\alpha$ equivalent width measurements or infrared photometry (see for instance Vallenari et al 1999).

5.3 Astrometric data

Tycho 2 provided proper motions measurements for four stars in the region of Bochum 11. Since the sample is very small, we refrain from any discussion, and simply report them in Table 7 for the sake of completeness. We only notice that HD 93632 has very high proper motion components, which may be due to measurement errors, since it is actually in a binary system. Looking at our photometric data there is no reason to believe that this star does not belong to Bochum 11.

6 CONCLUSIONS

We have presented the first $UBVRI$ CCD photometry for three star clusterings in the region of $\eta$ Carinae: Bochum 9, Bochum 10 and Bochum 11.

Bochum 9 is a puzzling object. It seems a group of 30 stars sharing common reddening located beyond the Carina spiral arm, although the projected spatial distribution and the poor kinematical data at disposal seem to imply that we are simply looking at a field star population.

Our analysis suggests that Bochum 10 is a very young and poorly populated open cluster. As many other young poor clusters, it is certainly an unbounded objects and will gradually disrupt. We provide estimates of interstellar reddening and distance compatible with previous studies.

As for Bochum 11, we find that it is a young open cluster, less than $4 \times 10^6$ yrs old, and confirm previous estimates for the cluster mean reddening and distance.

From our photometry we find indications of possible pre MS candidates in Bochum 9 and 11. This issue will be addressed in a forthcoming paper (Romaniello et al 2001), where $UBVRI$ photometry for all the other star clusterings known to lie in the Carina spiral feature will be presented and compared with theoretical models.

ACKNOWLEDGMENTS

This paper was based on observations made at ESO-La Silla. We acknowledge useful discussions with M. Zoccali, M. Rejkuba and A. Brown, GC thanks ESO for the kind hospitality. We are grateful to Drs. A. Feinstein and A.F.J. Moffat for giving us informations about the instrument set-up used to obtain their photoelectric photometry. The referee, Dr. J-C. Mermilliod, is deeply acknowledged for important suggestions, which led to improve the quality of the paper. Finally, this paper made use of Simbad and WEBDA.

APPENDIX A: PHOTOMETRIC SOLUTION AND ERRORS ESTIMATE

To allow for a precise photometric calibration we have observed five multistar fields from the list of Landolt (1992) each night during the observing run. After bias, flat-field corrections and exposure time normalization, the instrumental magnitudes of the standard stars were measured using the phottask in IRAF. To match Landolt’s observations we have used a 14” circular aperture. The same size has been used later to correct DAOPHOT magnitudes obtained for the scientific targets.

From these measurements we have computed the zero points and the colour terms of our photometric system via linear least squares fitting; the results are presented in Tab. A1. Since the airmass range covered by our observations was not large enough to secure a good determination of the extinction coefficients, we have adopted the average values for La Silla (cf. Patat 1999), which are also reported in Tab. A1.

The transformation from instrumental magnitudes to the standard Kron-Cousins system was obtained with expressions of the form

\[ M_i = m_i + zp_i + \gamma_i (M_i - M_j) - k_i z \]

(A1)

where \( M_i \), \( m_i \), \( zp_i \), \( \gamma_i \) and \( k_i \) are the calibrated magnitude, instrumental magnitude, zero point, colour term and extinction coefficient for the \( i \)-th passband and \( z \) is the airmass. The transformation requires of course the knowledge of the reference colour \( (M_i - M_j) \), which is easily computed from the instrumental magnitudes through the following relation:

\[ (M_i - M_j) = \frac{m_i - m_j + zp_i - zp_j - (k_i - k_j) z}{\gamma_{ij}} \]

(A2)

where we have set \( \gamma_{ij} = 1 - \gamma_i + \gamma_j \). If \( \sigma_{m_i}, \sigma_{zp_i}, \sigma_{\gamma_i} \) and \( \sigma_{k_i} \) are the RMS errors on the instrumental magnitude, zero point, colour term and extinction coefficient for the \( i \)-th passband, formal uncertainties on calibrated colors are then obtained propagating the various errors through Eq. A2 as follows:

\[ \sigma^2_{(M_i-M_j)} \sim \sigma^2_{m_{i,j}} + \sigma^2_{zp_{i,j}} + (M_i - M_j)^2 \sigma^2_{\gamma_{i,j}} \gamma_{i,j} \]

(A3)

For sake of simplicity, we have set \( \sigma^2_{m_{i,j}} = \sigma^2_{m_i} + \sigma^2_{m_j}, \sigma^2_{\gamma_{i,j}} = \sigma^2_{\gamma_i} + \sigma^2_{\gamma_j} \) and \( \sigma^2_{zp_{i,j}} = \sigma^2_{zp_{i}} + z^2 \sigma^2_{zp_{j}}. \)

Finally, the RMS uncertainties on the calibrated magnitudes are given by:

\[ \sigma^2_{M_i} \sim \sigma^2_{m_i} + \sigma^2_{zp_i} + (M_i - M_j)^2 \sigma^2_{\gamma_i} + \gamma_{i,j}^2 \sigma^2_{(M_i-M_j)} \]

(A4)

where we have neglected the error on \( z \) and assumed that the images in different passbands have been obtained at very similar airmass, as it was in fact the case.

Estimated uncertainties as a function of magnitude are reported in Tab. A2, from which it appears clearly that down to \( V \approx 17 \) they are dominated by the errors on the photometric solution, while at fainter magnitudes the contribution by the poissonian photon shot noise \( \sigma_{m} \) (estimated by DAOPHOT) becomes relevant.

As we have already discussed in Secs. 3, 4, and 5, the comparison with the data published by other authors has shown that some deviations exist for the stars which are common to the different data sets. Discrepancies on single

stars are probably due to the relatively large diaphragm coupled with the photoelectric photometer (11″-14″, Moffat and Feinstein, private communications). This is the case, for instance, for the star pairs #3-#6 and #6-#9 of Bochum 11, as it is shown in Fig. A1. One other example can be found in Carraro et al (2001) for NGC 3324.

On the other hand systematic deviations seem to exist. To investigate this problem we have analyzed the magnitude deviations as a function of magnitude and color for Bochum 10, for which a comparison with published data is possible in all pass-bands. The results are presented in Fig. A2, were the differences between our measurements and the results by Feinstein (1981) have been plotted as a function of \((B-V)\) (left panel) and \(V\) magnitude (right panel). With the only exception of the \(I\) filter, all pass-bands show small systematic deviations which are consistent with the estimated photometric errors. For \(I\) filter a color dependency seems to be there, and this would indicate the presence of an unaccounted colour term in the photoelectric measurements.
