Abstract

The GBAR experiment aims to measure the gravitational acceleration of antihydrogen $\bar{\text{H}}$. It will use $\bar{\text{H}}^+$ ions formed by the interaction of antiprotons with a dense positronium cloud, which will require about $10^{10}$ positrons to produce one $\bar{\text{H}}^+$. We present the first results on the positron accumulation, reaching $3.8(4) \times 10^8 e^+$ collected in 560 seconds.

1 Introduction

The GBAR collaboration’s aim is to measure the acceleration of antihydrogen atoms in the Earth’s gravitational field [1]. In the GBAR scheme, one first produces $\bar{\text{H}}^+$ ions [2], which are subsequently sympathetically cooled using

laser cooled Be$^+$ ions [3]. When the anti-ion is cold enough, the extra positron is removed using a laser pulse and the acceleration is derived by timing the subsequent annihilation products of the $\bar{H}$. The antiprotons are obtained from the ELENA decelerator at CERN [4], while positronium is produced by implantation of about $10^{10}$ positrons into a mesoporous silica film at a kinetic energy of 4 keV [5].

To obtain the necessary positrons, a 9 MeV LINAC accelerates electrons into a tungsten target equipped with a mesh moderator biased at 50 V. The resulting low energy positrons are then accumulated in a buffer gas trap (BGT) and transferred in a high field trap (HFT).

The BGT is a Penning-Malmberg trap based on the Greaves-Surko scheme [6], and was developed at CEA Saclay [7]. It uses N$_2$ as the trapping gas and CO$_2$ as a cooling gas. The trap is constructed from 3 sets of electrodes. In the first stage, inelastic collisions occur under a typical N$_2$ pressure of $10^{-3}$ mbar, whilst the second one is used for the accumulation at a typical N$_2$ pressure of $10^{-4}$ mbar, with the final stage used to store positrons for a dozens of seconds with a typical N$_2$ pressure of $10^{-6}$ mbar. The magnetic field in this trap is $\sim 0.05$ T and an electric potential between $-140$ V and $140$ V can be applied to the electrodes, as appropriate.

The HFT [8] is a 5 T Penning-Malmberg trap with 27 electrodes each able to hold potentials between $-1$ kV and 1 kV. The base pressure is lower than $10^{-9}$ mbar. This trap is used for long time storage.

In this article we present the outcome of optimisation studies to trap a large cloud of positrons. The final goal is to accumulate $10^{10}$ positrons in 100 s.

2 Studies of the trapping conditions

After an accumulation time $t$, using the potential profile shown in Figure 1b, the positron cloud is axially compressed, and then dumped on a target at the exit of the trap (Figure 1c). The positron number is estimated by detecting the $\gamma$ rays resulting from their annihilations on the target using a CsI detector. The signal is proportional to the number of accumulated positrons, which evolves as $N(t) = R\tau(1 - e^{-t/\tau})$, with $N$ the number of positrons, $\tau$ the lifetime and $R$ the trapping rate. Some accumulation curves for $e^+$ in the second stage are presented in Figure 2a for different N$_2$ pressures as measured at the injection point of the system. If $t \ll \tau$, $N(t) \approx Rt$, and the only parameter to optimise is then $R$. For the rest of the experiment we keep $P_{N_2} = 6$ mbar, with $\tau = 0.67(1)$ s and we accumulate for 100 ms before transferring to the third stage (Figure 1d).
**Figure 1:** On-axis potentials used in the Buffer Gas Trap. (a) Accumulation in the second stage. (b) Axial compression of the cloud. (c) Transfer from the second to the third stage. (d) Re-trapping. (e) Preparation for transfer / dumping. (f) Dumping.

**Figure 2:** (a) Number of $e^+$ as measured by the CsI detector, fit with $N(t) + c$. (b) $R$ vs $N_2$ pressure. (c) Positron annihilation rate ($\lambda = 1/\tau$) vs $N_2$ pressure. Pressures in mbar as measured at the injection point of the system.

Currently, the energy spread in the longitudinal direction of the incoming positrons is $\sigma = 8.8(3)$ eV but a spread of energy smaller than 3 eV would increase $R$ and therefore the overall efficiency.

In the third stage, the $e^+$ lifetime is 16.5(5) s, as shown in Figure 3a, and since this is much greater than 100 ms a stacking procedure of the positrons from the second stage can be done. Figure 3b shows that, using a static potential, only 6 stacks can be accumulated in the well in a linear way, beyond which the stacks are lost. It also shows that by lowering the bottom of the well by 0.2 V per stack, a dozen stacks can be accumulated without any loss. Therefore 10 stacks are accumulated in 1 s ($10 \times 100$ ms) before being transferred to the HFT.

To stack positrons from the BGT third stage in the HFT, one first uses a potential well made of 3 electrodes with $-10$ V as bottom of the well as shown in Figure 4a. Figure 4b shows that the well is saturated after 80
Figure 3: (a) Lifetime of positrons in the third stage. (b) Measurement of positron signal for different accumulation conditions in stage 3 (see text for details). The bottom of the well is lowered by dV between each stack.

stacks. To accumulate positrons in a linear way, a sequence is used in which the well is enlarged and deepened each time we approach a saturation limit. In the first well, 50 stacks are accumulated, after which the bottom of the well is lowered. Then 150 stacks are added, and again the bottom of the well is lowered and then a further 200 stacks are added. Finally we lower the bottom of the well to reach a maximum, so in total, we can accept 560 stacks of $e^+$ from the third stage corresponding to $3.8(4) \times 10^8 e^+$. We are planning to extend this process to trap even more positrons.

With the knowledge that the LINAC based positron source provides $1.54(6) \times 10^5 e^+$ per pulse at a frequency of 200 Hz, the current overall efficiency is 2.3%.

3 Conclusion

We succeeded in trapping $3.8(4) \times 10^8 e^+$ in 560 s, which is a first important step for the development of the GBAR experiment. Improvements will be
made in the coming months to reach our next step of $10^{10}$ positrons in a few hours, after which the goal will be to decrease this accumulation time, by increasing the $e^+$ flux at the entrance, and by improving efficiencies at the interfaces of the system.
