Respiratory syncytial virus (RSV) is an important human respiratory pathogen (Borchers et al., 2013). Infection with RSV manifests as a simple common cold in the majority of cases. However, in 2–3% of young children it leads to severe bronchiolitis and viral pneumonia, and it remains the major cause of infant hospitalization in the developed world. The variation in disease severity is caused by both host and viral factors and has previously been linked to polymorphisms in several innate immunity genes, including many that control the IFN system (Tal et al., 2004; Awomoyi et al., 2007; Janssen et al., 2007; Tulic et al., 2007; Siezen et al., 2009). IFNs may therefore be key regulators of RSV-induced lung inflammation, but it remains unclear which cell types and molecular pathways mediate IFN production in response to RSV infection and how IFNs then impact airway inflammation and bronchiolitis. Type I interferons (IFNs) are important for host defense from viral infections, acting to restrict viral production in infected cells and to promote antiviral immune responses. However, the type I IFN system has also been associated with severe lung inflammatory disease in response to respiratory syncytial virus (RSV). Which cells produce type I IFNs upon RSV infection and how this directs immune responses to the virus, and potentially results in pathological inflammation, is unclear. Here, we show that alveolar macrophages (AMs) are the major source of type I IFNs upon RSV infection in mice. AMs detect RSV via mitochondrial antiviral signaling protein (MAVS)–coupled retinoic acid–inducible gene 1 (RIG-I)–like receptors (RLRs), and loss of MAVS greatly compromises innate immune restriction of RSV. This is largely attributable to loss of type I IFN–dependent induction of monocyte chemokine–attractants and subsequent reduced recruitment of inflammatory monocytes (infMo) to the lungs. Notably, the latter have potent antiviral activity and are essential to control infection and lessen disease severity. Thus, infMo recruitment constitutes an important and hitherto underappreciated, cell-extrinsic mechanism of type I IFN–mediated antiviral activity. Dysregulation of this system of host antiviral defense may underlie the development of RSV-induced severe lung inflammation.

receptors (RLRs), RIG-I and melanoma differentiation–associated protein 5 (MDA5), sense atypical RNA species associated with viral infection (Liu et al., 2007; Loo et al., 2008; Yoboua et al., 2010; Goubau et al., 2013). Activated RLRs then signal through the adaptors, mitochondrial antiviral signaling protein (MAVS), to induce activation of transcription factors belonging to the nuclear NF-κB and IFN regulatory factor (IRF) families, which coordinate to act in the transcription of type I and III IFN genes. Type I IFNs can also be produced via an RLR–independent manner by cells that detect the extracellular presence of virions or virus-infected cells. In such cases, members of the TLR family are often involved and RSV has been shown to trigger TLR2, TLR3, TLR4, and TLR7/8 (Marr et al., 2013). Consistent with the fact that all cell types can be infected by viruses, every nucleated cell expresses RLRs and can produce type I IFNs via the cytosolic detection pathway. In contrast, the extracellular virus detection pathway via TLRs is predominantly active in immune cells, including macrophages and DCs, especially plasmacytoid DCs (pDCs). In the case of RSV, epithelial cells, fibroblasts, pDCs, alveolar macrophages (AMs), and conventional DCs have all been shown to produce type I IFNs after virus exposure in vitro (Jewell et al., 2007; Bhoj et al., 2008; Demoor et al., 2012; Schijf et al., 2013). Lung epithelial cells and pDCs have additionally been suggested to produce type I IFNs during experimental RSV infection in mice (Smit et al., 2006; Jewell et al., 2007). However, type I IFNs are notoriously difficult to detect in vivo as they are made only transiently. Thus, despite the genetic association between the type I IFN system and RSV disease, the cellular source of type I IFNs and the pathways leading to type I IFN production during RSV infection in vivo have not been truly elucidated.

Irrespective of source, all type I IFN species bind a single IFN-α/β receptor (IFNAR) expressed on all nucleated cells that signals through a JAK–STAT pathway to induce more than 300 IFN-stimulated genes (ISGs). These include components of the viral detection pathway themselves (e.g., RLRs), resulting in a positive feedback loop of virus–driven IFN production. ISGs also include a plethora of other genes whose products limit virus replication. For example, 2′–5′ oligoadenylate synthase 1 (OAS1), IFN-induced transmembrane protein 3 (IFITM3), or cyclic GMP-AMP synthase (cGAS) have all been shown to interfere with RSV replication.
and limit productive infection (Behera et al., 2002; Everitt et al., 2013; Goubau et al., 2013; Schoggins et al., 2014). The cell-intrinsic control of viral replication by ISG products is thought to be a major component of the antiviral state conferred by type I IFN exposure and to underlie the ability of IFNs to protect healthy cells from viral infection (Goubau et al., 2013).

Our group recently found that, in addition to acting to limit viral infection, IFNAR signaling is also critical for inducing lung inflammation in response to RSV infection in mice (Goritzka et al., 2014). In the absence of IFNAR, proinflammatory cytokines and chemokines were not produced in RSV-infected lungs (Goritzka et al., 2014). This observation suggested that type I IFNs act in lung innate immunity beyond promoting cell-intrinsic viral control, by inducing inflammation. Type I IFN–driven lung inflammation could be a bystander phenomenon or a cell-extrinsic means of controlling virus infection through the recruitment of antiviral inflammatory cells. Here, we address which lung cell populations produce type I IFNs during RSV infection in vivo and how this translates into viral control. We show that the MAVS-dependent RLR pathway in AMs accounts for almost all type I IFN production in the lungs of RSV-infected mice. MAVS-dependent type I IFN production by AMs induces local production of monocyte chemoattractants and leads to the recruitment of inflammatory monocyte (inMo)–derived cells to the lung. Notably, the recruited cells have potent and nonredundant antiviral effects, which are essential to limit lung viral load and decrease disease severity. Our work indicates an underappreciated monocyte–dependent cell-extrinsic mechanism underlying the antiviral action of type I IFNs and highlights the importance of balanced lung inflammation in early antiviral defense. Dysregulation of type I IFN–mediated inflammation might offset its beneficial function and underlie the development of severe RSV disease.

RESULTS
Identification of pulmonary cell populations producing type I IFNs in response to RSV
Type I IFNs are produced transiently after viral infection, and the identification of IFN-producing cells in vivo can be problematic. To identify type I IFN–producing cells in the lungs of mice infected with RSV, we used Ifna6gfp/+ mice, a transgenic model in which GFP is expressed under the control of the Ifna6 promoter (Kumagai et al., 2007). Mice were i.n. infected with $2 \times 10^6$ focus-forming units (FFU) of RSV and followed over time. First, we monitored the level of GFP expression. GFP signal was first detectable at 8 h in CD45+ leukocytes but not in CD45− cells (Fig. 1 A and not depicted). The percentage and number of GFP+ leukocytes increased steadily from 8 to 18 h postinfection (p.i.) and declined thereafter (Fig. 1 A). Thus, Ifna6gfp/+ mice appear to be a valid model for monitoring type I IFN expression in the lung after RSV challenge. The persistence of the GFP signal increases the likelihood of detecting relevant type I IFN–producing cells during the course of infection.

We assessed the presence of GFP signal in different lung cell types at 18 h p.i. by flow cytometry using the gating strategy shown in Fig. S1 (A and B). Although pDCs and epithelial cells are reported to be the main type I IFN producers during RSV infection (Smit et al., 2006; Jewell et al., 2007; Schijf et al., 2013), no GFP signal was detectable in either cell type (Fig. 1 B). Furthermore, there was no GFP expression in CD11b+ DCs, CD103+ DCs, CD64hi inflammatory cells, eosinophils, neutrophils, or endothelial cells (Fig. 1 B). In contrast, around 7% of AMs displayed a detectable GFP signal (Fig. 1, C and D). Analysis at different time points confirmed the presence of GFP signal exclusively among AMs (Fig. 1, C and D; and not depicted). Of note, AMs up-regulated CD11b, a marker not normally expressed on that cell type, during the course of infection and GFP+ AMs were all CD11bhi after day 2 p.i. (not depicted).

To independently validate these findings and measure additional type I IFN species, CD45− and CD45+ cells from naive or infected lungs from C57BL/6 mice were purified by cell sorting, and the levels of Ifna5 and Ifnb mRNA were determined by quantitative RT-PCR (Fig. 2 A; for gating see Fig. S1 B). Concordant with the earlier results in Fig. 1, CD45− stromal cells expressed limited amounts of Ifna5 and Ifnb when compared with CD45+ cells (Fig. 2 A). To distinguish among the latter, different lung leukocyte cell populations were purified by cell sorting from infected Ifna5gfp/+ mice (for gating strategy see Fig. S1, A and B). As expected, GFP+ AMs contained the highest levels of Ifna5 and Ifnb transcripts (Fig. 2 B). Low levels could also be detected in GFP− AMs and pDCs, arguing for slight underreporting in Ifna5gfp/+ mice. In conclusion, AMs account for the majority of type I IFN production in the lungs of RSV-infected mice with only a minor contribution from pDCs.

Type I IFN production by AMs in response to RSV infection is RLR–MAVS dependent
Next we dissected the pathway leading to type I IFN induction by lung AMs. Live virus was necessary as UV-inactivated RSV administered i.n. did not elicit GFP expression (Fig. 3 A). Importantly, live virus failed to induce a GFP signal in AMs from Ifna660/+ mice deficient in the RLR adaptor protein MAVS (Ifna660/+ Mavs−/− mice; Fig. 3 A). This was true at all time points examined, from 8 to 96 h p.i. (Fig. 3 B), demonstrating a key role for the RLR pathway in the AM response to RSV. Consistent with that notion, primary AMs isolated from Ifna660/+ mice but not from Ifna660/+ Mavs−/− mice secreted large amounts of IFN-α in response to increasing doses of RSV ex vivo (Fig. 3 C). The lack of IFN–α production by Ifna660/+ Mavs−/− AMs was maintained even when the cells were stimulated with RSV up to multiplicities of infection (MOIs) of 20 (not depicted).

A previous study using Newcastle disease virus showed that loss of IFN-α production in Mavs−/− AMs leads to compensatory IFN–α secretion by pDCs (Kumagai et al., 2007). In contrast, no compensatory GFP+ AM cell population was detectable at any time point (8 h to 9 d p.i.) in RSV-infected
et al. (2012), dance with previous studies by Bhoj et al. (2008) and Demoor lungs of the outcome of infection, we determined viral load in the To test whether loss of the type I IFN response to RSV affects MAVS controls the innate immune response to RSV shortly after infection in MAVS-sufficient was not observed in ISGs (Viperin, OAS-1, protein kinase R [PKR], or MX-1) with these results, induction of mRNAs encoding selected Type III IFNs (IFN-2/3) or IFN- was also not detectable 18 h p.i. in MAVS-sufficient Ifna5 and IFN-β in total lung homogenates of infected Ifna6gfp/+ Mavs−/− mice even though these cytokines were easily detected at 18 h p.i. in MAVS-sufficient Ifna6gfp/+ controls (Fig. 3 D). Type III IFNs (IFN-α2/3) or IFN-γ was also not detectable in the lungs of Ifna6gfp/+ Mavs−/− mice (Fig. 3 E). Consistent with these results, induction of mRNAs encoding selected ISGs (Viperin, OAS-1, protein kinase R [PKR], or MX-1) was not observed in Ifna6gfp/+ Mavs−/− mice but was detected shortly after infection in MAVS-sufficient Ifna6gfp/+ controls (Fig. 3 F). Altogether, these data suggest that type I IFN–dependent antiviral responses to RSV are primarily caused by triggering of the RLR–MAVS pathway in AMs.

**MAVS controls the innate immune response to RSV**

To test whether loss of the type I IFN response to RSV affects the outcome of infection, we determined viral load in the lungs of Ifna6gfp/+ (henceforth abbreviated WT) and Ifna6gfp/+ Mavs−/− (henceforth abbreviated Mavs−/−) mice. In accordance with previous studies by Bhoj et al. (2008) and Demoor et al. (2012), Mavs−/− mice had higher lung viral titers than control mice throughout the infection period and displayed delayed viral clearance (Fig. 4 A). Moreover, infection with RSV caused greater weight loss from day 6 until day 10 p.i. in Mavs−/− mice compared with MAVS-sufficient controls (Fig. 4 B). The bulk of the early inflammatory response to RSV infection was also strongly dependent on MAVS as transcripts encoding proinflammatory cytokines (e.g., TNF, IL-6, and IL-1β) were largely undetectable in lungs of Mavs−/− mice while being highly induced in control mice (Fig. 4 C; Bhoj et al., 2008). This is likely a secondary effect of the loss of type I IFNs as we have observed a similar phenotype in IFNAR1-deficient mice (Goritzka et al., 2014).

We further determined the effect of RSV infection on inflammatory cell recruitment to the lungs and extravasation into the airways. The recruitment of polymorphonuclear phagocytes, which occurs early after infection, was largely independent of MAVS as similar proportions and numbers of neutrophils were present in bronchoalveolar lavages (BALs; a representation of the airways) and lung cell suspensions from infected MAVS-sufficient and –deficient mice (Fig. 4 D and E). Consistent with this notion, substantial expression of the neutrophil chemoattractant Cxcl1 was detected early after infection in both WT and Mavs−/− mice even though levels were higher in the former group (Fig. 4 F). Similarly, Cxcl1 induction and unimpaired neutrophil recruitment was also observed in IFNAR1-deficient mice infected with RSV (Goritzka et al., 2014). The recruitment of T cells, including RSV-specific CD8+ T cells, detected at day 8 p.i., also did not differ between WT and Mavs−/− mice (Fig. 4, G–I; Bhoj et al., 2008; Demoor et al., 2012). In contrast, we noticed a large difference between WT and Mavs−/− mice in lung accumulation of CD64hi inflammatory cells after RSV infection.
In WT mice, leukocytes positive for CD64 and CD11b represented ~40% of the total leukocyte population at day 2 p.i., but those cells were completely absent in lungs of Mavs<sup>−/−</sup> mice at all time points (Fig. 5, A and B). Thus, MAVS deficiency results in a general impairment of inflammatory cytokine production and absence of CD64<sup>hi</sup> inflammatory cells in the lungs after RSV infection, but does not impact neutrophil or T cell recruitment.

**InfMos and monocyte-derived DCs (moDCs) are recruited to lungs of RSV-infected mice**

Phenotypic characterization of the CD64<sup>hi</sup> inflammatory cells recruited to the lungs of RSV-infected WT mice showed that most of these cells expressed Ly6C at day 1 p.i., suggestive of a monocytic origin. Ly6C expression was gradually down-regulated during the course of the infection (Fig. 5, C and D). Differential expression of CD11c further subdivided the CD64<sup>hi</sup> inflammatory cells into what has previously been described as moDCs (CD11c<sup>hi</sup>CD11b<sup>hi</sup>CD64<sup>hi</sup>; Fig. 5, C and E). The early recruited CD64<sup>hi</sup> inflammatory cells were a mix of CD11c<sup>hi</sup> moDCs and CD11c<sup>lo</sup> infMos, whereas most of the cells by day 2 p.i. were CD11c<sup>hi</sup> moDCs (Fig. 5 E). Interestingly, both moDCs and infMos produced TNF (Fig. 5, F and G; and not depicted; Shi and Pamer, 2011). Therefore, the lack of detectable TNF in the lungs of Mavs<sup>−/−</sup> mice infected...
Type I IFN regulation of immunity to RSV | Goritzka et al.

AMs promote the recruitment of CD64hi cells via type I IFN–dependent induction of monocyte chemoattractants

As MAVS−/− mice possess normal numbers of blood monocytes (not depicted), the failure of CD64hi inflammatory cells to accumulate in lungs after infection was likely caused by a deficiency in recruitment. The chemoattractants CCL2, CCL7, and CCL12 (all ligands for CCR2) are critical for monocyte recruitment to inflamed tissues (Shi and Pamer, 2011). We found that all three chemokines were induced in lung tissue shortly after RSV infection in WT but not in MAVS−/− mice (Fig. 7, A and B). Type I IFNs have been implicated in the induction of CCL2 (Iijima et al., 2011; Majer et al., 2012; Conrady et al., 2013), and consistent with that notion, IFNAR1-deficient mice also failed to produce and
with AM transfer did not reach the level observed in control-infected WT mice, it was nevertheless sufficient to partially restore accumulation of CD64 hi inflammatory cells (Fig. 7, E and F) and lead to increased expression of TNF (Fig. 7 G).

In a second approach, Mavs−/− mice were given a single administration of recombinant (r) IFN-α i.n. 6 h p.i. to mimic type I IFN secretion by AMs in WT mice. This was sufficient to induce expression of Ccl2 (Fig. 8 A) and to partially restore recruitment of CD64 hi inflammatory cells (Fig. 8, B and C) and lung TNF levels (Fig. 8 D). Finally, in a third approach, we bypassed type I IFNs entirely and directly administered rCCL2 to the airways of Mavs−/− mice. After one dose of rCCL2 given 6 h p.i., CD64 hi inflammatory cells were attracted to the lungs of RSV-infected Mavs−/− mice (Fig. 8 E).

Figure 5. MAVS-dependent recruitment of TNF-producing CD64 hi inflammatory cells to RSV-infected lungs. (A) Representative plots of CD11b hiCD64 hi inflammatory cells in the lungs of mock (PBS)- or RSV-infected WT or Mavs−/− mice 18 h p.i. with RSV. (B) Quantification of CD64 hi inflammatory cells in the lungs of WT and Mavs−/− mice during infection. Data are mean ± SEM of four to five mice per group. (C) Representative plots of Ly6C and CD11c expression on CD64 hiCD11b hi inflammatory cells (gated as in Fig. S1 A) at the indicated time points after RSV infection of WT mice. (D) Representative histograms of Ly6C expression on CD64 hiC11b hi inflammatory cells at the indicated time points p.i. of WT mice. (E) Quantification of the total number of CD64 hi cells split into CD11c hi (moDCs; black) or CD11c lo (infMos; gray) at the indicated time points p.i. of WT mice. Data are mean ± SEM of five mice per group. (F) Number of TNF-positive CD64 hiCD11c hi moDCs in the lungs of WT or Mavs−/− mice at the indicated time points p.i. 0 h represents mock (PBS)-infected mice. Expression was determined by intracellular staining for TNF and flow cytometry analysis. Data are mean ± SEM of five mice per group. (G) Ex vivo production of TNF secreted into culture supernatants by total lung cells and FACS-sorted CD64 hiCD11c hi moDCs isolated from WT mice at 18 h p.i. Each point represents one individual experiment using cells pooled from 25–40 mice. In A–F, the data are representative of at least two independent experiments. Statistical significance of differences between WT and Mavs−/− mice at different time points was determined by unpaired Student’s t test. **, P < 0.01; ***, P < 0.001.

secretes CCL2 (Fig. 7 C) or recruit CD64 hi infMos to the lung after RSV infection (not depicted). We therefore hypothesized that the absence of CD64 hi inflammatory cell accumulation in the lungs of RSV-infected Mavs−/− mice and lack of local TNF production is caused by impaired monocyte recruitment through failure of AMs to produce type I IFNs and consequent lack of local induction of monocyte chemoattractants. To test this hypothesis, we first transferred WT AMs i.n. into Mavs−/− mice 24 h before RSV infection. This transfer led to an increase in CCL2 mRNA (48 h p.i.) in the lungs of Mavs−/− mice that had been reconstituted with WT AMs as compared with Mavs−/− mice that received Mavs−/− AMs (Fig. 7 D). Although the induction of CCL2 achieved with AM transfer did not reach the level observed in control-infected WT mice, it was nevertheless sufficient to partially restore accumulation of CD64 hi inflammatory cells (Fig. 7, E and F) and lead to increased expression of TNF (Fig. 7 G).

In a second approach, Mavs−/− mice were given a single administration of recombinant (r) IFN-α i.n. 6 h p.i. to mimic type I IFN secretion by AMs in WT mice. This was sufficient to induce expression of Ccl2 (Fig. 8 A) and to partially restore recruitment of CD64 hi inflammatory cells (Fig. 8, B and C) and lung TNF levels (Fig. 8 D). Finally, in a third approach, we bypassed type I IFNs entirely and directly administered rCCL2 to the airways of Mavs−/− mice. After one dose of rCCL2 given 6 h p.i., CD64 hi inflammatory cells were attracted.
to the lungs (Fig. 8, E and F), and local production of TNF was restored (Fig. 8 G). NK cells were not recruited to lungs of the Mavs⁻/⁻ mice with or without administration of rCCL2, acting as a control for specificity (Fig. 8 H). Together, these data indicate that AMs promote the recruitment of CD64⁺ inflammatory cells to the lungs of RSV-infected mice through production of type I IFNs, which results in local induction of CCL2 and other monocyte chemoattractants and recruits CCR2⁺ monocytes.

**CD64⁺ inflammatory cells limit viral replication and disease severity**

To address the role of the recruited CD64⁺ inflammatory cells, we evaluated their contribution to disease severity, as measured by weight loss. As noted earlier, RSV-infected Mavs⁻/⁻ mice showed greater weight loss than controls (Figs. 4 B and 9 A). Notably, this was completely prevented by prior transfer of WT but not Mavs⁻/⁻ AMs (Fig. 9 A). Weight loss in mice correlates with increased viral load (Pribul et al., 2008). Indeed, RSV viral load was significantly lower in Mavs⁻/⁻ mice that received WT AMs compared with Mavs⁻/⁻ mice that were given Mavs⁻/⁻ AMs (70–85% reduction of RSV N and L gene copies; Fig. 9 B). As the transfer of WT AMs into Mavs⁻/⁻ mice results in type I IFN production, which can have pleiotropic and direct antiviral effects, we also used a depletion approach and found that viral load was increased in anti-CCR2–treated monocyte-depleted C57BL/6 mice despite normal production of type I IFNs (67–70% increase in RSV L and N gene copies; Fig. 9 C).

Finally, we administered rCCL2 to Mavs⁻/⁻ mice to examine the ability of CD64⁺ inflammatory cells to control disease in a setting that does not impact type I IFN induction. Remarkably, three doses of rCCL2 given during the course of infection almost completely prevented weight loss in Mavs⁻/⁻ mice (Fig. 10 A). Viral load was also decreased as assessed by the measurement of L and N gene copies at days 2 (40–55% reduction in RSV N and L gene copies) and 4 p.i. (45–75% reduction in RSV N and L gene copies; Fig. 10 B). This is likely a large underestimate of the antiviral effect of CCL2 treatment because some of the antiviral effects of type I IFNs manifest themselves at points in the viral life cycle other than generation of viral RNA (such as, for example, viral packaging and budding [Goubau et al., 2013]). Indeed, when actual viral titers were measured (by an immunoplaque assay), lungs of Mavs⁻/⁻ mice contained 100-fold higher virus levels at day 4 p.i. than controls, and this was nearly completely normalized by CCL2 treatment (Fig. 10 C). We conclude that the type I IFN–dependent influx of CD64⁺ inflammatory cells into the lungs of RSV-infected mice is both necessary and sufficient to limit RSV replication and diminish disease severity. Indeed, it accounts for most of the resistance to RSV infection conferred by MAVS.

**DISCUSSION**

Type I IFNs can be produced by many cell types in response to virus encounter. They act through the IFNAR to induce a large number of genes encoding inhibitors of viral replication and virus assembly that together mediate cell-intrinsic resistance to virus infection and protect from viral spread. Genetic association studies have implicated a role for the type I IFN system in severe lung inflammation induced by RSV infection in some individuals. However, the cellular origin of those type I IFNs and the physiological role of type I IFN–induced inflammation remains unclear. Here, we show that AMs are responsible for production of type I IFNs during lower respiratory tract RSV infection and use the RLR–MAVS pathway for RSV detection. Notably, loss of type I IFN production by AMs results in increased viral...
In a mouse model of RSV infection, we found that the major source of type I IFN is in fact AMs. AMs have a crucial role in maintaining lung homeostasis and clearing airway debris (Hussell and Bell, 2014). Their strategic positioning at the air–liquid interface also places them at key sites of respiratory virus entry. Indeed, AMs have been shown to produce type I IFN after Newcastle disease virus and influenza A virus infection (Kumagai et al., 2007; Helft et al., 2012). Our data add to the notion that AMs are part of a rapid innate first line of defense against invading lung pathogens.

We found that the ability of AMs to rapidly respond to RSV depends on the adaptor protein MAVS, consistent with studies suggesting that RSV can be recognized through both RIG-I and MDA5 (Liu et al., 2007; Bhoj et al., 2008; Loo et al., 2008; Yoboua et al., 2010; Demoor et al., 2012). This also suggests that AMs are directly exposed to infectious virus in vivo as engagement of the RLR pathway requires viral RNA presence in the cytosol. Interestingly, RSV has been shown to infect AMs ex vivo, but infection does not result in production of infectious viral particles (Ravi et al., 2013). This suggests that AMs are naturally resistant to RSV replication, replication and exacerbated disease. However, this is not fully attributable to loss of cell-intrinsic viral control but, rather, is associated with lack of recruitment of monocyte-derived inflammatory cells. We further show that these inflammatory cells are both necessary and sufficient to mediate type I IFN–dependent control of RSV infection and to control RSV-induced pathology. Thus, our data reveal an underappreciated facet of type I IFN–dependent resistance to viral infection that operates in a cell-extrinsic fashion through rapid recruitment of antiviral inflammatory cells to sites of infection.

Most cells can produce type I IFNs, and epithelial cells, macrophages, fibroblasts, and pDCs have all been suggested as possible sources of these cytokines in response to RSV challenge (Jewell et al., 2007; Bhoj et al., 2008; Demoor et al., 2012). Most of those conclusions were based on studies involving in vitro exposure of cells to the virus, which may or may not reproduce virus accessibility in vivo. Using a mouse model of RSV infection, we found that the major source of type I IFN is in fact AMs. AMs have a crucial role in maintaining lung homeostasis and clearing airway debris (Hussell and Bell, 2014). Their strategic positioning at the air–liquid interface also places them at key sites of respiratory virus entry. Indeed, AMs have been shown to produce type I IFN after Newcastle disease virus and influenza A virus infection (Kumagai et al., 2007; Helft et al., 2012). Our data add to the notion that AMs are part of a rapid innate first line of defense against invading lung pathogens.

We found that the ability of AMs to rapidly respond to RSV depends on the adaptor protein MAVS, consistent with studies suggesting that RSV can be recognized through both RIG-I and MDA5 (Liu et al., 2007; Bhoj et al., 2008; Loo et al., 2008; Yoboua et al., 2010; Demoor et al., 2012). This also suggests that AMs are directly exposed to infectious virus in vivo as engagement of the RLR pathway requires viral RNA presence in the cytosol. Interestingly, RSV has been shown to infect AMs ex vivo, but infection does not result in production of infectious viral particles (Ravi et al., 2013). This suggests that AMs are naturally resistant to RSV replication,
with that notion and previous data (Haeberle et al., 2001; Miller et al., 2004; Culley et al., 2006), we noticed that there is robust induction of CCL2, CCL7, and CCL12 in the lungs and recruitment of monocyte-derived cells early after RSV infection. This was not observed in Mavs−/− mice, but it was not a direct consequence of impaired RLR signaling in AMs. Rather, CCL2 production in several infection models is strongly dependent on type I IFN (Crane et al., 2009; Seo et al., 2011; Majer et al., 2012; Conrady et al., 2013), and we showed that the lack of type I IFN underlies the loss of CCL2. The cellular source of CCL2 during RSV infection in vivo is not known. A radioresistant cell type has been implicated in CCL2 production during HSV-1 infection of the cornea which may allow them to maintain sentinel activity while escaping the cytopathic effects of infection. Abortive viral replication may also render AMs less susceptible to the effect of the viral NS protein, which inhibits RLR activity (Spann et al., 2004; Ling et al., 2009; Boyapalle et al., 2012). NS protein–dependent blockade of the type I IFN responses could explain why lung epithelial cells do not register in our assays as a major source of type I IFN despite being the prevalent target of RSV infection and replication.

Local neutrophil and monocyte recruitment is a hallmark of inflammation. It occurs in response to chemokine production induced by inflammatory cytokines or by signals from receptors that detect infection or tissue injury. Consistent with that notion and previous data (Haeberle et al., 2001; Miller et al., 2004; Culley et al., 2006), we noticed that there is robust induction of CCL2, CCL7, and CCL12 in the lungs and recruitment of monocyte-derived cells early after RSV infection. This was not observed in Mavs−/− mice, but it was not a direct consequence of impaired RLR signaling in AMs. Rather, CCL2 production in several infection models is strongly dependent on type I IFN (Crane et al., 2009; Seo et al., 2011; Majer et al., 2012; Conrady et al., 2013), and we showed that the lack of type I IFN underlies the loss of CCL2. The cellular source of CCL2 during RSV infection in vivo is not known. A radioresistant cell type has been implicated in CCL2 production during HSV-1 infection of the cornea.
The type I IFN–inducible monocyte chemoattractants mediate recruitment of monocyte-derived CD64hi inflammatory cells, which make up as much as 40% of total lung leukocytes at day 2 after RSV infection and can be identified by high expression of CD11b and CD64. The latter has been argued to be a better marker than Ly6C for detection of monocyte progeny in the lung (Plantinga et al., 2013). Indeed, we found that Ly6C expression was down-regulated during the course of infection, especially from days 3 to 4 p.i. onwards. The CD64hi inflammatory cells can be subdivided into CD11clo and CD11chi cells, representing infMos and moDCs, respectively (Shi and Pamer, 2011; Segura et al., 2013). Interestingly, CD11c expression on the CD64hi inflammatory cells increased during infection, and almost all CD64 hi cells were positive for CD11c after day 2 of infection. CD11c up-regulation has been interpreted as a sign of infMo conversion into moDCs, also known as Tip-DCs or inflammatory DCs (Conrady et al., 2013), and ex vivo infection using RSV elicited CCL2 production from both AMs and primary airway epithelial cells (Demoor et al., 2012). A possible source of CCL2 may be AMs themselves responding to their own type I IFN production through signaling via IFNAR, consistent with the notion that macrophages can be a source of monocyte chemoattractants (Deshmane et al., 2009).
Type I IFN regulation of immunity to RSV | Goritzka et al.

The figure legends mention a cell-extrinsic mechanism of action of type I IFNs. CD64hi inflammatory cells in the early T cell–independent response to RSV. Interestingly, we observed that CD64hi inflammatory cells play a major role in restricting virus production and dampening disease severity. Similarly, monocyte-derived cells have recently been shown to limit HSV-2 and HSV-1 replication in the vaginal tract and in the cornea, respectively (Iijima et al., 2011; Conrady et al., 2013).

The nature of the antiviral mechanism, whether it resides within the CD11chi or CD11clo population and how it limits disease severity remains unclear. It is possible that the antiviral activity is mediated in part by the production of TNF and/or inducible nitric oxide synthase (iNOS), consistent with the original function ascribed to Tip-DCs (Serbina et al., 2003). Increased RSV load has been observed in mice treated with anti-TNF (Rutigliano and Graham, 2004), and TNF can limit RSV replication in human lung epithelial cells (Merolla et al., 1995). Consistent with this notion, CD64hi inflammatory cells in our model produced TNF and their absence led to a major loss of TNF in total lung extracts. Nitric oxide has also been implicated in monocyte-dependent antiviral control in a model of HSV-1 infection of the eye (Conrady et al., 2013). However, we failed to see an effect of iNOS inhibition on RSV lung titers in C57BL/6 mice (unpublished data) even though a study in BALB/c mice reported that it could increase infection (Stark et al., 2005). Another possibility could be that CD64hi inflammatory cells express TNF–related apoptosis-inducing ligand (TRAIL) and kill RSV-infected epithelial cells, as reported for influenza virus infection (Herold et al., 2008; Lin et al., 2008; Davidson et al., 2014), and CCL2 is increased in nasal secretions or BAL of children with RSV bronchiolitis (Garofalo et al., 2001; Welliver et al., 2002; McNamara et al., 2005). Lungs are particularly delicate, and unbridled inflammation at those sites can block gas exchange, with disastrous consequences for the host. Therefore, the production of type I IFNs and recruitment of antiviral monocytes during RSV infection must be carefully balanced to reduce viral load but not allow excessive cell infiltration. It is interesting to speculate that genetically or environmentally driven alterations to this balance possibly underlie the susceptibility of some human patients to RSV-induced bronchiolitis and pneumonia. MATERIALS AND METHODS Mice. C57BL/6 mice were purchased from Charles River or Harlan Laboratories, Inc. Ifnar1−/− mice on a C56BL/6 background were obtained from C. Reis e Sousa (London Research Institute, London, England, UK). Ifnα60 transgenic mice and Ifnα60 mice deficient in MAVS (Mavs−/−; Kumagai et al., 2007) were used as heterozygotes (Ifnα60+/−). For all experiments in which GFP is not a primary readout (Fig. 4 onwards), the Ifnα60+/− mice are designated as WT mice and Ifnα60−/− Mavs−/− as Mavs−/− mice for simplicity and to denote the fact that the mice may or may not have a copy of the gfp insert at the Ifnar1 locus. In all experiments with genetically modified mice (e.g., Mavs−/− mice), littermates were always used as the control groups (e.g., WT mice). All mice were bred and maintained in pathogen-free conditions, and gender- and age-matched mice aged 7–12 wk were used for each experiment. All animal experiments were reviewed and approved by the Animal Welfare and Ethical Review Board (AWERB) within Imperial College London and approved by the UK Home Office in accordance with the Animals (Scientific Procedures) Act 1986 and the ARRIVE guidelines. Virus and infections. Plaque-purified human RSV (originally A2 strain from the ATCC) was grown in HEP-2 cells (Lee et al., 2010). Inactivation was performed by exposing virus to UV light for 2 min in a CX-2000 UV
 cross-linker (UV). For infection, mice were lightly anesthetized and instilled i.n. with 5–2 × 10^9 FFU of RSV in 100 µl. In some instances, this was followed by i.n. instillation of recombinant proteins (500 ng/mouse IFN-α/11 [Miltenyi Biotech] and 25 µg/mouse rCCL2 [PeproTech] at 6 h p.i. For experiments monitoring the effect of CCL2 on weight loss and viral load day 4 p.i., rCCL2 (25 µg/mouse) was additionally given i.n. at 18 and 48 h p.i. For monocyte depletion, the anti-CCR2 antibody MC21 or an IgG2b isotype-matched control of irrelevant specificity (BD) was administered i.p. at 20 µg/mouse 6 h before and then daily during infection (Mack et al., 2001). For AM transfer into MAVS-deficient mice, 4–5 × 10^5 AMs was followed by i.n. instillation of recombinant proteins (500 ng/mouse RSV in 100 µl. In some instances, this was further incubated i.n. with 1.5–2 × 10^6 FFU of RSV in 100 µl. In some instances, this was >98% assessed by flow cytometry.

Isolation of lung cells. Mice were sacrificed at different times p.i. and perfused with PBS. To obtain lung leukocytes, lung lobes were collected into a C-Tubes (Miltenyi Biotech) containing complete DMEM (dDMEM; supplemented with 10% fetal bovine serum, 2 mM l-glutamine, 100 U/ml penicillin, and 100 µg/ml streptomycin), 1 mg/ml Collagenase D (Roche) and 30 µg/ml DNase I (Invitrogen) and processed with a gentleMACS dissociator (Miltenyi Biotech) according to the manufacturer’s protocol. Shredded tissue was incubated for 1 h at 37°C. After lysis of red blood cells, cells were strained through a 100-µm filter (BD). To obtain epithelial and endothelial cells, lung tissue, stained as described above. Cells were then sorted using a standard BD FACSAria III equipped with a 488-nm laser and the anti–CD11c microbeads (Miltenyi Biotech). The positively selected cell fractions were stained as described above. Cells were then sorted using a standard BD Aria III equipped with 50–mW 405-nm, 50–mW 488-nm, 50–mW 514-nm, 50–mW 633-nm lasers and an ND1.5 filter in front of the FSC photodiode. Acquisition was set to 250,000 live cells. For intracellular staining for TNF, surface-stained and fixed cells (as described above) were stained with fluorochrome-conjugated anti-RSV antibody (Biogenes). Infected cells were detected using Streptavidin (Sigma–Aldrich) and DAB substrate (diaminobenzidine tetrahydrochloride), enumerated by light microscopy and used to calculate titer as FFU.

BAL cell processing. To determine the cellular composition of the BAL, cells were transferred onto a microscope slide (Thermo Fisher Scientific) using a Shandon Cytospin 3 centrifuge, and slides were stained with hematoxylin and eosin (H&E; Reagena, Gamidor). Cells were categorized as macrophages, lymphocytes, neutrophils, and eosinophils based on morphology and size under a light microscope (Axio; Carl Zeiss; Durant et al., 2014).

Flow cytometry. For staining, cells were first incubated for 30 min with a fixable live-dead Aqua dye (Invitrogen), followed by incubation for 20 min with a purified rat IgG2a anti–mouse CD16/CD32 receptor antibody (BD) to block Fc binding. Cells were then stained with fluorochrome-conjugated antibodies against CCL11 (H13, PE-CF594), CCL14 (M70/10, AF700), CD45 (30-F11, eFluor780), Ly6C (HK.14, eFluor450), CD103 (2E7, PerCP-Cy5.5), Siglec-H (MP6-XT22, BV650) in the presence of purified rat IgG2a–mouse CD16/CD32 receptor in BD permeabilization buffer for 60 min at 4°C. Samples were analyzed on a BD LSRFortessa-SORP equipped with 20–mW 355-nm, 50–mW 405-nm, 50–mW 488-nm, 50–mW 514-nm, 20–mW 633-nm lasers and an ND1.5 filter in front of the FSC photodiode. Acquisition was set to 250,000 live cells. All antibodies were purchased from BD, BioLegend, or eBioscience. Data were analyzed with FlowJo software (Tree Star).

FACS. For CD45−/− lung cell sorting, cells were, after digestion of the lung tissue, stained as described above. For leukocyte cell sorting, lung single cell suspensions were incubated for 20 min with a purified rat IgG2b anti–mouse CD16/CD32 receptor antibody, after which CD11c enrichment was performed by incubating the lung cells with anti–CD11c microbeads (N418; Miltenyi Biotec) for 15 min on a shaker and positive selection on an autoMACS Pro Separator (Miltenyi Biotech). In some cases, the negative fraction was further processed to enrich for CD11c−/− pDCs using anti–PDCA1 microbeads (Miltenyi Biotech). The positively selected cell fractions were stained as described above. Cells were then sorted using a standard BD Aria III equipped with 50–mW 405-nm, 50–mW 488-nm, 50–mW 514-nm, 20–mW 633-nm lasers and an ND1.5 filter in front of the FSC photodiode, a nozzle size of 100 µm, and corresponding BD FACSFlow sheath pressure of 20 psi, matched with a transducer frequency of 29 kHz. Input pressure was adjusted to ensure that every fifth to sixth drop was populated by an event. FACS-sorted cells were cultured overnight (see below) or stored in Trizol until RNA extraction was performed.

RNA isolation and quantitative RT-PCR. Total RNA was isolated from lung tissue using an RNeasy Mini kit (QIAGEN) according to the manufacturer’s instructions. RNA extraction from sorted cells was performed using Trizol (Invitrogen) according to the manufacturer’s instructions. After the chloroform step, the aqueous phase–containing RNA was further processed using the RNeasy Mini kit (QIAGEN) according to the manufacturer’s instructions. 1 µg RNA (total lung) or 9 µl (FACS-sorted cells) was reverse transcribed using a High Capacity RNA-to-cDNA kit (Applied Biosystems) according to the manufacturer’s instructions. To quantify mRNA levels in lung tissue, quantitative RT-PCR reactions for Ifnα/2/3, Ifnb, Tnfβ, Ifng, Eif2ak2, Oas1a, Oas2/3, and RsvL L and N gene were performed using primers and probes as previously described (Culley et al., 2002; Perkins et al., 2005; Lee et al., 2010; Slater et al., 2010; Bartlett et al., 2012; Goritzka et al., 2014). Analysis was performed using the Quant iT Probe PCR Master Mix (QIAGEN) and the 7500 Fast Real-Time PCR System (Applied Biosystems). For absolute quantification, the exact number of copies of the gene of interest was calculated using a plasmid DNA standard curve, and the results were normalized to levels of Gapdh, a housekeeping gene (Applied Biosystems). For relative quantification, the expression of Ifna5, Mc1r, Ccl2, Cox11, C11r, C11r2, B6, and Ifih (all from Applied Biosystems) was expressed relatively to the expression of Gapdh. First, the ∆CT (Ct−cycle threshold) between the target gene and Gapdh for each sample was calculated, after the calculation of 2−∆∆CT. Analysis was performed using 7500 Fast System SDS Software (Applied Biosystems).

Chemokine and cytokine detection. Lungs were placed in protease inhibitor cocktail (Roche) on ice and homogenized using a TissueLyser (QIAGEN). Homogenate was centrifuged for 10 min, 10,000 g at 4°C, and chemokine and cytokine quantification was then performed on the supernatant.
For chemokine and cytokine quantification in the airways, BAL fluid was collected by flushing the lungs three times with 1 ml PBS supplemented with 5 mM EDTA (Life Technologies). For ex vivo AM stimulation, 1.25 × 10^6 AMs/well were seeded into 96-well plates. After 2 h at 37°C, cells were washed and exposed to different MOIs of RSV. After 20 h, supernatants were collected for cytokine analysis. The concentration of CCL2 was measured using mouse DuoSet ELISA (R&D Systems) according to the manufacturer’s instructions. IL-6 was detected by ELISA using MPS-20F3 capture antibody and biotinylated MPS-32C11 detection antibody (both from BD). IFN-α was detected by ELISA as previously described (Asselin-Paturel et al., 2001). Data were acquired on a SpectraMax Plus plate reader (Molecular Devices) and analyzed using SoftMax software (version 5.2). IFN-α and IFN-β levels were determined using a Procarta Immunoassay (Affymetrix). Data were acquired with a Bio-Plex 200 system (Bio-Rad Laboratories). The concentration of cytokines in each sample was determined by reference to a standard curve using the Bio-Plex 6 software (Bio-Rad Laboratories). For ex vivo production of TNF by moDCs, FACSD-sorted moDCs or total lung cells from 18 h p.i. were seeded at 10^6 cells/well in cDMEM. After 18-h incubation at 37°C, supernatants were assessed for TNF presence by Luminox (20-Plex Luminox kit; Life Technologies).

**Statistical analysis.** Statistical analysis was performed using Prism 6 (GraphPad Software). Two group comparisons were performed using unpaired, two-tailed Student’s t test. One-way ANOVA with Tukey’s post hoc test was used to compare multiple groups, and two-way ANOVA with Bonferroni’s post hoc test was used for time-kinetic comparison of weight loss. Data are expressed as the mean ± SEM, and for all tests a value of P < 0.05 was considered as significant. * P < 0.05; ** P < 0.01; *** P < 0.001; ns, not significant.

**Online supplemental material.** Fig. S1 shows gating strategy for identifying and sorting lung cell populations using flow cytometry. Online supplemental material is available at http://www.jem.org/cgi/content/full/jem.20140825/DC1.

We thank Peter Openshaw for advice and continuous support. We also thank Caetano Reis e Sousa and Maite Paulsen for critically reading the manuscript. We thank the National Institutes of Health Tetramer Core Facility for RSV M187–195 tetramers (H-2Db/NAITNAKII) and staff of the St. Mary’s Flow Cytometry Facility and the Animal Facility for their assistance.
