Neglected zoonotic agents in cattle abortion: tackling the difficult to grow bacteria

Sara Vidal 1,2, Kristel Kegler 3, Gilbert Greub 4, Sebastien Aeby 4, Nicole Borel 5, Mark P. Dagleish 6, Horst Posthaus 3, Vincent Perreten 1 and Sabrina Rodriguez-Campos 1*

Abstract

Background: Coxiella burnetii, Chlamydia abortus and Leptospira spp. are difficult to grow bacteria that play a role in bovine abortion, but their diagnosis is hampered by their obligate intracellular lifestyle (C. burnetii, C. abortus) or their lability (Leptospira spp.). Their importance is based on the contagious spread in food-producing animals, but also as zoonotic agents. In Switzerland, first-line routine bacteriological diagnostics in cattle abortions is regulated by national law and includes only basic screening by staining for C. burnetii due to the high costs associated with extended spectrum analysis. The aim of this study was to assess the true occurrence of these zoonotic pathogens in 249 cases of bovine abortion in Switzerland by serology (ELISA for anti-C. burnetii and C. abortus antibodies and microscopic agglutination test for anti-Leptospira spp. antibodies), molecular methods (real-time PCR and sequencing of PCR products of Chlamydiaceae-positive cases), Stamp’s modification of the Ziehl-Neelsen (mod-ZN) stain and, upon availability of material, by histology and immunohistochemistry (IHC).

Results: After seroanalysis the prevalence was 15.9% for C. burnetii, 38.5% for C. abortus and 21.4% for Leptospira spp. By real-time PCR 12.1% and 16.9% of the cases were positive for C. burnetii and Chlamydiaceae, respectively, but only 2.4% were positive for C. burnetii or Chlamydiaceae by mod-ZN stain. Sequencing of PCR products of Chlamydiaceae-positive cases revealed C. abortus in 10% of cases and the presence of a mix of Chlamydiaceae-related bacteria in 5.2% of cases. Pathogenic Leptospira spp. were detected in 5.6% of cases. Inflammatory lesions were present histologically in all available samples which were real-time PCR-positive for Chlamydiaceae and Leptospira spp. One of 12 real-time PCR-positive cases for C. burnetii was devoid of histological lesions. None of the pathogens could be detected by IHC.

Conclusion: Molecular detection by real-time PCR complemented by histopathological analysis is recommended to improve definitive diagnosis of bovine abortion cases and determine a more accurate prevalence of these zoonotic pathogens.

Keywords: Coxiella burnetii, Chlamydiaceae, Leptospira spp., Bovine abortion, Zoonosis
possible role in abortion in ruminants as well as in humans [7–11]. 

C. burnetii has a wide host range, including domestic and wild animals. Infection in most animals is subclinical or presents with non-specific clinical signs, whereas ruminants, the main reservoir of infection, may present with late abortion and stillbirths; moreover, C. burnetii might be associated with metritis and infertility in cattle [3, 12–18]. Human infection with C. burnetii is known as Q fever and can lead to miscarriage in women [19–21]. Leptospirosis is caused by Gram-negative, pathogenic spirochetes of the genus Leptospira that is divided in more than 250 pathogenic serovars worldwide, which are classified into 25 serogroups on the basis of their serological phenotype. In cattle, leptospirosis is mainly associated with reproductive problems including infertily, low conception rate, abortion, stillbirths and weak offspring [22–24]. Cattle are considered to be the maintenance host of serovar Hardjo resulting in a high degree of subclinical infections [25]. Human leptospirosis occurs worldwide, is transmitted via direct or indirect contact with urine from infected animals and is due mostly to recreational and occupational activities [26–28]. Numerous outbreaks of leptospirosis worldwide have been also associated with heavy rainfall and flooding [29, 30]. Abortion in women due to leptospirosis may occur if infection takes place during pregnancy [31, 32].

Given the numerous possible etiologies of abortion in ruminants and the high cost of definitive diagnosis, a finance-limited investigation is performed usually, and the causative agent often remains undetermined [33]. Of the three cattle abortifacient pathogens discussed, only investigation of C. burnetii is legally regulated in Switzerland requiring Stamp’s modification of the Ziehl-Neelsen (mod-ZN) stain [34] of tissue smears [Ordinance on Epizootic Diseases (TSV) SR.916.401; Article 129].

According to the epizootics database of the Swiss Federal Food Safety and Veterinary Office (InfoSM www.infosm.blv.admin.ch, consulted on 02/08/2017), 676 cases of coxiellosis in cattle were reported from 2006 to 2016. Although pathogenic Leptospira spp. and C. abortus are not included in routine bovine abortion diagnostics and, moreover, Leptospira interrogans serovar Hardjo is exempt from mandatory notification in cattle, 43 cases of leptospirosis and 23 cases of chlamydiosis in cattle were reported in the same time frame.

In this study, the recommended mod-ZN method was complemented with serology, molecular methods, histology and immunohistochemistry to determine the degree of underestimation of the three abortifacient pathogens C. burnetii, C. abortus and pathogenic Leptospira spp. in bovine abortion in Switzerland.

Methods

Collection of samples

Samples from 249 cases of bovine abortion from different cantons of Switzerland were collected from October 2012 to October 2015 [Bern (n = 213), Vaud (n = 7), Fribourg (n = 6), Jura (n = 6), Solothurn (n = 6), Aargau (n = 2), Basel-Land (n = 2), Neuchâtel (n = 2), Valais (n = 2), Zurich (n = 2) and Luzern (n = 1)]. The 249 cases comprised 242 placentas, 57 fetal abomasal contents and 182 maternal sera submitted for routine abortion diagnostics. Placenta from a healthy calf was included as a negative control.

Stamp’s modification of the Ziehl-Neelsen stain

Smears of placentas, abomasal contents (n = 299) and the negative control placenta were subjected to mod-ZN staining [32] and examined by light microscopy. Chlamydia-positive placental tissue was included as positive control in every stain. The sample was considered positive for Chlamydiales and/or C. burnetii when intracytoplasmic red-stained coccobacilli appeared in clumps against a blue background. The technique does not allow a differentiation between Chlamydiales and C. burnetii.

Serological studies

The 182 maternal sera were tested for antibodies against C. burnetii and C. abortus using the commercial CHEKIT® Q fever antibody ELISA Test Kit and CHEKIT® C. abortus Antibody Test Kit (IDEXX, Liebefeld-Bern, Switzerland) according to the manufacturer’s instructions. The results were expressed as S/P values and derived from the ratio between optical density (OD) of the sample (S) and the OD of positive control (P) included in the kits. IDEXX state an S/P ≥ 40% is considered positive, an S/P < 30% is considered negative, and S/P values between these are considered suspect positive.

The serological detection of antibodies against Leptospira spp. was performed by microscopic agglutination test (MAT) (Manual of Diagnostic Tests and Vaccines for Terrestrial Animals of the Ordinance of Epizootic Diseases [22]). Twelve serovars were included in the test panel: Australis, Autumnalis, Ballum, Bataviae, Bratislava, Canicola, Grippotyphosa, Hardjo, Icterohaemorrhagiae, Pomona, Sejroe and Tarassovi (Additional file 1: Table S1). Sera were screened initially for agglutination at a dilution of 1:100 in sterile 0.85% NaCl. Reactive sera were titrated in two-fold serial dilutions to determine the end-point titer defined as the dilution at which at least 50% agglutination occurs. In every serological analysis negative and positive control sera were included as controls.
DNA extraction and molecular studies

For the extraction of total genomic DNA 2 g of placenta or 2 mL of fetal abdominal content were suspended in 5 mL 0.85% NaCl in an IKA® DT-20 tube [35] and homogenized twice for 30 s at 6000 rpm, using the IKA ULTRATURRAX® tube drive. Subsequently, 500 μL of the homogenates were used for DNA extraction using QIAamp Mini Kit (Qiagen, Hombrechtikon, Switzerland). Fluorometric quantification of DNA was performed by Quantus™ Fluorometer (Promega, Dübendorf, Switzerland).

Real-time PCR targeting the IS1111 of C. burnetii was performed according to Howe et al. [36]: IS1111-F801: 5′-AATTTCATCGTTCCCGGCAAG 3′; IS1111-R901: 5′-GCCGCGTTTACTAATCCCCCA 3′; probe IS1111-p8225-MGB: 5′-6FAM-TGTCGGCGTTTATTGG-MGBNFQ 3′. PCR was performed in a total volume of 25 μL, 1X final concentration of TaqMan Universal PCR Master Mix, 1 μM of each primer, 0.5X of internal positive control (IPC) Template, 0.5X IPC Mix and 2.5 μL of the template. The following conditions were applied: 94 °C for 2 min, 45 cycles of 94 °C for 15 s and 60 °C for 30 s. Amplification was performed in duplicate on the TaqMan 7500 Fast Real-time PCR System (Applied Biosystems, Zug, Switzerland). As positive and negative controls C. burnetii DNA and water were used, respectively. Samples were considered positive when showing an exponential amplification curve up to cycle 39 in both replicates.

A pan-Chlamydiales real-time PCR targeting the Chlamydiales 16S rDNA was performed according to Lienard et al. [37]: panCh16F2: 5′-CCGGCAAACACTGGGACT3′; panCh16R2: 5′-GGAGTTAGCGCGTGCTTCTTAC3′; probe panCh16S: 5′-6FAM-CTACGGGAGGCTGCTGGAATC-MGBNFQ 3′. PCR assays were performed in 20 μL, with iTaq Supermix with ROX (Bio-Rad, Reinchach, Switzerland), 0.1 μM concentrations of each primer (Eurogentec, Seraing, Belgium), a 0.1 μM concentration of probe (Eurogentec), molecular-biology-grade water (Sigma-Aldrich, Buchs, Switzerland) and 5 μL of DNA sample. The cycling conditions were 3 min at 95 °C, followed by 50 cycles of 15 s at 95 °C, 15 s at 67 °C and 15 s at 72 °C. Samples were tested in duplicate using a StepOnePlus™ Real-time PCR System (Applied Biosystems, Foster City, CA, USA). As positive and negative controls C. abortus DNA and water were used, respectively. Samples were considered positive when showing an exponential amplification curve up to cycle 40 in both replicates. Samples exhibiting a cycle threshold (Ct) of ≤35 cycles were sequenced using specifically designed internal sequencing primers as described by Lienard et al. [37]. Obtained sequences were edited and analyzed by BLAST on the NCBI website (http://www.ncbi.nlm.nih.gov).

Real-time PCR targeting the lipL32 gene of Leptospira spp. was performed using primers and probe described by Villumsen et al. [38]: LipL32-F: 5′-AGAGGTTCTT-TACAGAATTTCTTCTACTACCT 3′; LipL32-R: 5′-TGGGAAAGACAGACAAAACAAG 3′; probe LipL32-P: 5′-6FAM-AAGTAGATCTTTGCATTGCC-MGBNFQ 3′. PCR was performed in a total volume of 25 μL, 1X final concentration of TaqMan Universal PCR Master Mix, 1 μM of each primer, 80 nM of the probe, 0.5X of IPC Template and 0.5X IPC Mix and 2.5 μL of the template. The following conditions were applied: 94 °C for 2 min, 45 cycles of 94 °C for 15 s and 60 °C for 30 s using the TaqMan 7500 Fast Real-time PCR System. DNA of Leptospira spp. serovar Icterohaemorrhagiae strain RGA and water were used as positive and negative controls, respectively. Samples were considered positive when showing an exponential amplification curve up to cycle 40 in both replicates.

Histopathology

To assess the significance of the molecular analysis, all cases with real-time PCR-positive results were examined histopathologically and by IHC (n = 32) when the placental tissue was available and was not severely autolytic. Selected samples of placenta were fixed in buffered formalin (10%), processed routinely through graded alcohols and embedded in paraffin-wax. Sections (4 μm) were mounted on Thermo Scientific™ SuperFrost Plus® (Braunschweig, Germany) slides and stained with hematoxylin and eosin (HE) for histological evaluation.

Antibodies

For immunohistochemistry, mouse monoclonal anti-Coxiella burnetii antibody (clone 3.13, Squarix GmbH, Marl, Germany) diluted 1:500 in Tris-buffered saline (TBS), an anti-Chlamydiaceae-specific antibody directed against the chlamyidal lipopolysaccharide (LPS, Clone ACI-P, Progen, Heidelberg, Germany) diluted 1:200 in antibody diluent (Glostrup, Denmark) and a rabbit polyclonal anti-LipL32 antibody (kindly provided by Dr. Jarlath Nally) diluted 1:1000 in phosphate-buffered saline (PBS) for detection of pathogenic Leptospira spp. were used.

Immunohistochemistry (IHC)

All real-time PCR-positive cases for C. burnetii (n = 13), Chlamydiales (n = 14) and Leptospira spp. (n = 5) were subjected to immunohistochemistry when tissue was available and not autolytic.

Briefly, for all three antibodies 4 μm thick sections were deparaffinized and rehydrated through graded alcohols.

For C. burnetii, sections were immersed in 3% H2O2 in methanol (v/v) for 20 min to quench endogenous
tissue peroxidases. Non-specific antibody binding was blocked with 25% normal goat serum (NGS, Vector Laboratories, Peterborough, UK) in TBS for 30 min and incubated with the primary antibody overnight at 4 °C. Visualization of the bound anti-C. burnetii primary antibody was by EnVision Kit (goat anti-mouse horse-radish peroxidase conjugate, DakoCytomation, Ely, UK) according to the manufacturer’s instructions followed by addition of the chromogen 3-amino, 9-ethyl-carbazole (AEC, Vector Laboratories, Peterborough, United Kingdom) for 10 min.

Chlamydiaceae immunohistochemistry was performed as described by Borel et al. [39] using the detection kit Dako ChemMate (Dako, Glostrup, Denmark).

Immunohistochemistry for pathogenic Leptospira spp. was performed using the avidin-biotin-peroxidase complex (ABC) method. Sections were treated with 0.5% H2O2 in methanol (v/v) for 30 min to block endogenous peroxidase, heated in sodium-citrate buffer for 30 min in the microwave for antigen retrieval, incubated with 20% goat serum for 30 min, then incubated with the respective primary antibody overnight at 4 °C. Biotinylated goat-anti-rabbit IgG (BA-1000) diluted 1:200 in PBS (Vector Laboratories, Burlingame, CA, USA) was used as secondary antibody with incubation time of 60 min. Colour development was with 3,3′-diaminobenzidine tetrahydrochloride (DAB) with H2O2 (0.03%, pH 7.2) for 5 min.

Sections immunolabeled with the respective primary antibodies against Chlamydiaceae, C. burnetii and pathogenic Leptospira spp. were all counterstained with hematoxylin prior to mounting in an appropriate mountant.

Four qPCR-negative cases for all three agents were included as negative controls. For C. burnetii and pathogenic Leptospira spp., primary antibodies were substituted with an isotype matched normal mouse IgG antibody or normal rabbit IgG (1:3000; R4505; Sigma Aldrich, Taufkirchen, Germany), respectively, as method negative control preparations.

Sections of intestinal tissue from gnotobiotic piglets experimentally infected with porcine Chlamydia suis strain S45/6, C. burnetii-positive sheep and human placentas and hamster kidney infected with L. interrogans serovar Hardjo JB191 were included as positive controls.

**Statistical analysis**

We calculated the degree of agreement between the serological and the molecular tests for C. burnetii, C. abortus and Leptospira spp. carried out in 182 cases using Cohen’s kappa (κ) coefficient with 95% of CIs with the online software GraphPad (http://graphpad.com/quickcalc/kappa2). Standard cutoffs were used to define poor (κ < 0.40), fair (κ = 0.41–0.60), good (κ = 0.61–0.80) and very good agreement (κ ≥ 0.80). The techniques that do not allow for detection of a specific pathogen or yielded only negative results were not included in the comparison.

**Results**

**Stamp’s modification of the Ziehl-Neelsen stain**

Of the 299 tissue smears, 10 placental smears and two of abomasal contents were positive as denoted by the presence of red intracytoplasmic organisms consistent with coccobacilli. One of the positive placentas and abomasal content samples were from the same case (Additional file 2: Table S2).

**Detection by serological analysis**

Of the 182 sera tested, 29 (15.9%) were positive for C. burnetii and two (1.1%) were suspect positive. Chlamydial antibodies were detected in 70 (38.5%) of the 182 sera and 23 (12.6%) sera were suspect positive. The prevalence of antibodies against Leptospira spp. was 39/182 (21.4%), with 21 (11.5%) sera being positive for at least two serovars. Serovar Hardjo was the most frequent (31/39) followed by serovar Sejroe (14/39). Yet, 12 sera were positive for both serovars with 10 sera showing a higher titer for Hardjo and, hence, indicating that the latter is the causative serovar. Six cases were positive for serovar Australis (Table 1).

**Detection by molecular analysis**

Real-time PCR detection of C. burnetii was positive in 28/242 (11.6%) placenta and 7/57 (12.3%) abomasal content samples. The pan-Chlamydia real-time PCR was positive for 41/242 placenta (16.9%) and 2/57 (3.5%) abomasal content samples. The results after amplicon sequencing of positive samples with a Ct ≤ 35 are summarized in Table 2. C. abortus was detected in 24 placenta samples and in one abomasal content sample. New Chlamydia-related bacteria were detected in four placenta samples. All four were distantly related to known species but all four could be assigned to the Parachlamydiaceae family since they exhibited >90% similarity with at least a member of this clade. The sequencing of the remaining 12 samples was not discriminatory because of superposition of sequences, probably due to the presence of more than one member of the Chlamydiales order in the sample. Real-time PCR for the detection of Leptospira spp. was positive for 14/242 (5.8%) samples of placenta and 1/57 (1.8%) samples of abomasal contents. For seven of the samples positive by real-time PCR, serum for analysis by MAT was available and was positive in five cases (serovar Hardjo, n = 4; serovar Icterohaemorrhagiae, n = 1) and negative in two cases. All the results of the molecular analyses are...

included in Additional file 2: Table S2 and the percentage of positive placenta and abomasal content samples is summarized in Fig. 1.

To compare serological and molecular techniques we analyzed 182 cases that were processed by ELISA, MAT and PCR (Fig. 2). All three pathogens had more positive results in the serological analyses than in the molecular analysis, with *C. abortus* having the highest seropositivity. Results from samples that were positive by real-time PCR for more than one pathogen are summarized in Table 3.

**Histopathology and IHC**

The severity of the placentitis, necrosis, inflammatory cell infiltrate and vasculitis in all real-time PCR-positive cases of *C. burnetii*, *Chlamydiales* and *Leptospira* spp. that were evaluated histologically (when tissue was available and not autolytic) varied greatly and the histological findings are summarized in Table 4.

Regardless of the etiological agent, if necrosis was present in the cotyledon it was multifocal, randomly distributed and affected the chorioallantoic stroma and the villi including the trophoblasts.

Placentitis was present in 12 of 13 samples that were positive for *C. burnetii* by real-time PCR. Necrosis was present in 11 of 13 cases. Mixed inflammatory infiltrates characterized by neutrophils, macrophages and lymphocytes were present in nine of 13 cases and only three cases were designated as suppurative placentalitis. Vasculitis was present in five of 13 cases and characterized by infiltration of neutrophils, macrophages and lymphocytes primarily in the tunicae media and adventitia resulting in mild fibrinoid necrosis only (Fig. 3a). All cases positive for *Chlamydiales* by real-time PCR had placentalitis and necrosis. Mixed inflammatory cell infiltrates were present in 12 of 14 cases, only one was designated supplicative and one case was infiltrated by macrophages and lymphocytes (mononuclear) only. Vasculitis was present in seven of the 14 cases (Fig. 3b). Similarly, all cases of *Leptospira* spp. positive by real-time PCR had placentalitis and necrosis (Fig. 3c). Mixed inflammatory cell infiltrates were present in three of five cases, while in two cases the inflammation was comprised of mononuclear leukocytes only. For cases positive for *Leptospira* spp. by real-time PCR no suppurative placentalitis was found and only one case had vasculitis.

Immunohistochemical analysis failed to visualize *C. burnetii*, *Chlamydiales* and *Leptospira* spp. in all sections evaluated (Table 4).

**Statistical analysis**

The Cohen’s kappa coefficient is summarized in Table 5. The degree of agreement between the serological and the molecular diagnostic techniques for *C. burnetii*, *C. abortus* and *Leptospira* spp. was poor with $\kappa = 0.103 \pm 0.086$, $\kappa = -0.006 \pm 0.067$ and $\kappa = 0.163 \pm 0.074$, respectively.

**Discussion**

This study investigated, concomitantly, the prevalence of *C. burnetii*, *C. abortus* and pathogenic *Leptospira* spp. DNA in bovine abortion material and seroconversion in affected dams and highlights the underestimation associated with using a single staining technique. Although detection of any of these pathogens does not equate invariably to causality with respect to bovine abortion, their presence does invariably represent a high zoonotic risk and a possible reservoir of infection for other animals.

The frequency of antibodies specific for *C. burnetii* in dams was 15.9%, comparable to the reported seroprevalence of 16.7% in aborting cows in Switzerland by Hässig
and Lubsen [40]. However, previous studies reported similar seropositivity for \textit{C. burnetii} antibodies but in healthy cows and in different European countries (Bulgaria 20.8%; France 15%; Germany 19.3% and the Netherlands 21%) [41] suggesting serological results are not reliable for diagnostic purposes. With 38.4% positive and 13.0% suspect positive reactions the seropositivity to anti-\textit{C. abortus} antibodies was the highest of the three abortifacient pathogens investigated in this study. This result was in agreement with studies in other countries which also reported a high prevalence of anti-chlamydial antibodies in cattle, with seropositivity ranging from 45% to 100% [42]. However, such high seropositivity rates have to be interpreted with caution. Firstly, a single seropositive result is not necessarily related to the etiology of the abortion and might be due to a previous exposure [43]. Secondly, serological tests may not be \textit{C. abortus} specific and positive titers can arise from cross-exposure [44]. The frequency of \textit{Leptospira} spp. antibodies was 21.4% and primarily due to serovar Hardjo (seroprevalence of 17.0%). The implication of a positive titer to serovar Hardjo on fetal loss remains controversial as many studies failed to show a causal association between seropositivity and abortion [22, 45–48], while others described Hardjo as a cause of abortions [49, 50]. The interpretation of the serological results for \textit{Leptospira} spp. should be done carefully since there is cross-reactivity between serovars of the same serogroup; nevertheless, the infecting serovar is more likely to show the higher titer [22, 51]. Although Sejroe was the second most prevalent serovar (14 cases), 12 cases were positive for serovars Hardjo and Sejroe, belonging to the same serogroup. Yet, Hardjo presented the higher titer in 10 cases making Australis (six cases) the second most frequent serovar. Abortion in cattle due to serovar Hardjo is a chronic event with a variable serological response at the time of abortion [22] and confirmation of infection by MAT is difficult because maternal antibody production mostly occurs prior to fetal death [52].

Molecular detection of DNA of abortifacient agents has been shown to be highly sensitive and specific [37, 53–55]. By real-time PCR we detected \textit{C. burnetii} in 12.1% of cases, similar to findings in Italy (11.3%) obtained by nested PCR [56] but lower than results by classical PCR from Portugal (17.2%) [57] and by real-time PCR from Hungary (25.9%) [58]. These findings, although obtained with different techniques, may reflect different endemicity. Furthermore, we showed the capacity of \textit{C. burnetii} of spreading via the amniotic-oral route [59, 60] with the 7/57 samples of abomasal content being positive. Of the 21 real-time PCR positive cases of \textit{C. burnetii}, 15 were seronegative suggesting early stages of infection when antibodies are not yet present, or environmental contamination of samples or failure of the dam to seroconvert occurred. In contrast, 23 cases with positive sera were negative by real-time PCR suggesting previous exposure to \textit{C. burnetii} is not uncommon. The statistical analysis showed a poor agreement (κ = 0.103 ± 0.086) between the serological and the molecular technique indicating that there is a poor relationship between the seropositivity of the dam for antibodies to \textit{C. burnetii} and an abortion event as reported previously [61–64]. It is important to keep in mind that real-time PCR is highly sensitive and thus able to detect low levels of \textit{C. burnetii}. Yet, different strains harbor a very variable number of the target IS1111 (between 7 and 110) making quantification inaccurate for this bacterium [65]. For the final interpretation at herd-level it is recommended to include complementary techniques and consider the case history [18, 66].

Of 43 real-time PCR-positive samples for \textit{Chlamydiales} (placenta, n = 41; abomasal content, n = 2) \textit{C. abortus} could be identified by sequencing in 9.6% of the cases, although the prevalence could be higher because in 12 samples a single species could not be assigned due to

multiple peaks. In Eastern Switzerland, *C. abortus* was considered not to play an important role in bovine abortion in studies by end-point PCR [39] and real-time PCR [67]. However, Blumer et al. [9] confirmed the presence of *C. abortus* in 14.8% of studied cases of abortion from Eastern Switzerland. We could detect members of the *Parachlamydiaceae* family in four samples confirming that *Chlamydia*-related bacteria could be involved in bovine abortion as reported previously [9, 39, 67] and could cause mixed infection [68]. It is noteworthy that some samples with *Chlamydia*-related bacteria, including *P. acanthamoebae*, were positive by *C. abortus* ELISA also. This result might be due to the production of antibodies that could cross-react with other chlamydial species due to a genus-specific epitope of the lipopolysaccharide [44, 69–71]. This might also be the underlying reason for the poor agreement (∕ = −0.006 ± 0.067) between the serological and the molecular technique.

*Presence of intracytoplasmic bacteria (ICB). Presence of extracellular bacteria (ECB)*
In six cases of coxiellosis we found evidence of coinfection with *C. abortus* and *Chlamydiales*-related bacteria. Although *C. burnetii* and *Chlamydiales* belong to phylogenetically unrelated species [72], they have some similarities in their interaction with the host and mechanisms of pathogenicity [73]. Thus, the diagnosis of either agent is usually established by microscopic examination of stained placenta smears in veterinary diagnostic laboratories but this cannot discriminate between the different organisms. Pritchard et al. [74] stated that the mod-ZN stain is insufficiently sensitive in cattle cotyledons. Our findings agree with this and confirm that the mod-ZN stain is not very sensitive for the detection of either *C. burnetii* or *Chlamydiales* in infection in bovine abortion material and that it should be replaced by specific real-time PCRs.

Pathogenic *Leptospira* spp. had a prevalence of 5.6% by real-time PCR (placenta, *n* = 14; abomasal content, *n* = 1). The detection of leptospires in internal organs of aborted or stillborn fetuses reflects chronic leptospirosis of the mother and indicates an active infection of the fetus, but PCR-based diagnosis of leptospirosis alone cannot identify the infecting serovar; moreover, contamination with faeces or autolysis in clinical samples is known to lead to false-negative results [22]. Hence, the combination of both, molecular and serological techniques is of epidemiological value, even though no satisfactory agreement between techniques (κ = 0.163 ± 0.074) was achieved. Unfortunately, in only seven cases material was available for both analysis, and four sera of these were positive for serovar Hardjo and one for serovar Icterohaemorrhagiae. Two of the samples positive by real-time PCR for *Leptospira* spp. DNA were negative in MAT indicating an early stage of the infection or failure to detect seroconversion. In one case, pathogenic *Leptospira* spp., presumably identified as serovar Hardjo by serology, were detected together with *C. burnetii* and *Chlamydiales* and in another case we found possible coinfection between pathogenic *Leptospira* spp. and *C. abortus*.

Histological investigation and confirmation of the cellular inflammatory process indicative of infectious agents is important to unambiguously confirm the implication of a specific etiological agent especially if it could also be present in the commensal and the environmental microbiota [43]. However, as the cotyledonal lesions are not pathognomonic for any of the three pathogens investigated [39, 75], a definitive diagnosis based on histopathology only is not possible. Accordingly, in real-time PCR-positive cases of *C. burnetii* and *Chlamydiales* we found similar placental lesions varying only in the degree and severity of the inflammatory infiltrate. Although, vasculitis in the placenta of abortion cases is described as a prominent feature of *C. abortus* infections [39], it is not invariably present. Furthermore, vasculitis in the placenta is present frequently in cases of *C. burnetii* abortion [75, 76] as was observed in this study.

### Table 5

|                      | C. burnetii | C. abortus | Leptospira spp. |
|----------------------|-------------|------------|-----------------|
| Number of observed agreements | 145 (79.67% of the observations) | 103 (56.59% of the observations) | 146 (80.22% of the observations) |
| Number of agreements expected by chance | 140.7 (77.33% of the observations) | 103.5 (56.85% of the observations) | 139.0 (6.37% of the observations) |
| Kappa (κ)            | 0.103 ± 0.086 | −0.006 ± 0.067 | 0.163 ± 0.074 |
| 95% CIs              | −0.065 to 0.272 | −0.137 to 0.126 | 0.018 to 0.308 |
| Strength of agreement| Poor         | Poor        | Poor            |

Fig. 3 Histopathology of representative placental samples from bovine abortions positive by real-time PCR for: *Coxiella burnetii* (**a**), *Chlamydia abortus* (**b**) and pathogenic *Leptospira* spp. (**c**). Infection with either *C. burnetii* (**a**) or *C. abortus* (**b**) was characterized by variable degrees of vasculitis (arrow) and necrosis (arrowhead). Cases positive for pathogenic *Leptospira* spp. by real-time PCR (**c**) showed variable severities of necrosis (arrowhead) and lacked vasculitis. HE, bar 100 μm.
Additionally, we found that not all *Chlamydiales* real-time PCR-positive cases displayed vasculitis, similar to previous reports [9, 39]. All *Leptospira* spp. real-time PCR-positive cases showed necrotizing placentitis with three and two displaying mixed and mononuclear inflammatory infiltrates, respectively. Vasculitis was not observed in any sample except one case which was real-time PCR-positive for *C. burnetii* and *Chlamydiales* also. Placental lesions caused by *Leptospira* spp. in bovine abortion are not well characterized but, based on our limited observations, vasculitis is not a prominent feature.

Lesion-associated pathogen detection is usually considered vital for definitive diagnosis to prove causality. However, we were not able to identify lesion-associated *C. burnetii, Chlamydiales* or *Leptospira* spp. by IHC in any of the analyzed slides. IHC is known to have lower sensitivity than real-time PCR [77, 78], especially when there is some degree of autolysis in the samples as is often the case for abortion material.

Limited first-line diagnostics (mod-ZN staining) could only detect possible abortifacient agents in 11 cases (4.4%) while real-time PCR detected a possible abortifacient agent in 78 cases (31.2%). The fact that (i) *C. burnetii, Chlamydiales* and *Leptospira* spp. are all difficult to culture, (ii) serology cannot exclude a past infection or confirm an ongoing infection and (iii) IHC apparently fail to demonstrate the presence of the agents, makes the molecular approach the method of choice.

**Conclusions**

In conclusion, we recommend an extended workflow including molecular analysis for routine abortion diagnostics to avoid the underestimation of the discussed agents and histological analysis to avoid misinterpretation of real-time PCR positive results. It would be prudent to use molecular methods initially and then subject positive cases to histological screening. For further epidemiological investigations complementary serological analyses should be considered. However, the real value of this work was dependent on verifying lesion-associated agents in 78 cases (31.2%). The fact that (i) *C. burnetii, Chlamydiales* and *Leptospira* spp. are all difficult to culture, (ii) serology cannot exclude a past infection or confirm an ongoing infection and (iii) IHC apparently fail to demonstrate the presence of the agents, makes the molecular approach the method of choice.

### Acknowledgements

The authors would like to thank Dr. Jarlath Nally ( Infectious Bacterial Diseases Research Unit, National Animal Disease Center, Agricultural Research Service, United States Department of Agriculture, Ames, Iowa, USA) for kindly providing the LipL32-antibody and are grateful to Valentine Jaquier, Isabelle Brodard and Stefanie Müller for technical assistance.

### Funding

This study was financed by project 1.14.07 of the Swiss Federal Food Safety and Veterinary Office. Additional funding was obtained from the Institute of Veterinary Bacteriology, University of Bern and from the Scottish Government Rural and Environment Science and Analytical Services Division (RESAS).

### Availability of data and materials

The datasets generated and analyzed during the current study are not publicly available. However, the data can be available from Authors upon request.

### Authors’ contributions

SRC and VP conceived the study. SV and SRC were responsible for the study coordination and the data and sample collection. SV and SRC were responsible for the serological analyses and the real-time PCR of *C. burnetii* and *Leptospira* spp. SA and GG were responsible for the real-time PCR and sequencing of samples for *Chlamydiales*. KK and HP were responsible for pathological and histological investigation and immunohistochemistry for *Leptospira* spp. NB was responsible for immunohistochemistry of *Chlamydiaceae*. MPD was responsible for immunohistochemistry of *C. burnetii*. SV drafted the manuscript. SRC and MPD edited the manuscript. All of the authors read and approved the final manuscript.

### Ethics approval and consent to participate

All samples included in this study were received as routine diagnostic submissions for the screening of abortions as prescribed by law.

### Consent for publication

Not applicable.

### Competing interests

The authors declare that they have no competing interests.

### Publisher’s Note

Springer Nature remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.
