Introduction

Arsenite is a toxic metalloid that is widely distributed in the environment found in water, soil, and air. Exposure to inorganic arsenite occurs worldwide via environmental (e.g., contaminated drinking water, air, food, domestic fuel sources) and occupational exposures (e.g., smelting industries, pesticide production)[9]. In addition to its association with nonmalignant diseases, arsenic is a major world-wide health concern because of its carcinogenic potential in humans[8-10].

As part of the innate immune defense, the polarized conducting lung epithelium acts as a biological barrier to keep exogenous particulates carried in respiration from underlying tissue. Arsenite is a metalloid toxicant that can increase the variety of pulmonary adverse health effects, such as lung inflammation, fibrosis, emphysema and tumors via inhalation or ingestion[11]. Since the lung is an important target organ for inorganic arsenite-induced carcinogenicity[8], pulmonary toxicity has not been fully elucidated. Human A549 epithelial lung adenocarcinoma cells were routinely used as in vitro model system for lung epithelial cells[9,10]. We hypothesize that sodium arsenite can cause cell toxicity in A549 cells via programmed cell death. To test the hypothesis we will determine the biological responses of sodium arsenite on the lung epithelial cells by monitoring arsenite-induced toxicity, particularly programmed cell death via autophagy and apoptosis.

Keywords: Sodium arsenite (NaAsO2); Lung epithelial cells; Oxidative stress; Programmed cell death
Materials and Methods

Reagents and materials

Trivalent Inorganic Arsenic Sodium meta arsenite [NaAsO₂], MW 129.91, abbreviated as iASIII (purity > 98%), phenylmethylsulfonyl fluoride (PMSF) and protease inhibitor cocktail were supplied by Sigma-Aldrich (St. Louis, MO). Trivalent Inorganic Arsenic Sodium meta arsenite was dissolved in double-distilled water to a final concentration of 10⁻² M. This stock solution was freshly prepared for every test. Serial dilutions were prepared starting from the stock solution to obtain different arsenite concentrations in cell media.

Cell culture

The A549 cell line was derived from human lung carcinoma of a 58-year-old Caucasian male[11] which has been routinely used as a model for lung epithelial cells[12]. It is known to have retained a number of the main characteristics of the native lung epithelium[13] such as tight junctions formation, presence of keratin, and synthesis of ferritin[14]. Cells were cultured in a complete, consisting of RPMI 1640 medium, supplemented with 10% fetal bovine serum (FBS), 100 μg /ml penicillin, and 100 μg/ml streptomycin and maintained at 37 °C and 5% CO₂ in a humidified incubator.

Preparation of sodium arsenite solution

Trivalent Inorganic Arsenic (sodium arsenite) was dissolved in double-distilled water to a final concentration of 10⁻² M. This stock solution was freshly prepared for every test. Serial dilutions were prepared starting from the stock solution to obtain different arsenite concentrations in cell media.

Analysis of cell viability by MTT assay

MTT assay was used to evaluate the viability of A549 cells cultured in media containing different concentrations of sodium arsenite (0.00, 0.625, 1.25, 2.50, 5.00, 10.0, 20.0, 40.0, 80.0 μM) according to the instruction of the manufacturer’s instruction. Briefly, 1.00 x 10⁴ of A549 cells were seeded into 96-well plates overnight to adhere, and the media containing various concentrations of sodium arsenite was added to the wells. After incubation for 24h and 48h, MTT 5mg/ml, equal of 1/10 of media, was added to each well and incubated for 3 h. After incubation, the medium was removed, and equal media of DMSO was added to the remaining precipitates on the plates in the well. The absorbance of the resulting solution was determined at 570 nm (690 nm wavelength was used as reference) using a spectrophotometer (BIO-RAD).

Reactive oxygen species (ROS) assay

The intracellular ROS production levels were determined using an oxidation sensitive fluorescent dye, 2’7’-dichlorodihydrofluorescein diacetate (H2DCFDA). Briefly, after starvation, cells were treated with different concentrations sodium arsenite (0 - 20 uM) for 24 hours. After washing, the cells were incubated with 40 μM DCFH-DA for 45 min in dark. At the end of DCFH-DA incubation, cells were washed with PBS, Lyased with 1N NAOH, and aliquots were transferred to a blackwell plate (BD Falcon). The fluorescent intensity was measured using a multidetection microplate reader (FLUO star Optima Microplate Reader, BMG LABTECH, Cary, NC) with excitation and emission wavelengths of 485 nm and 520 nm, respectively. Three independent experiments were conducted.

Autophagy assay by AO staining

As a marker of autophagy, the volume of the cellular acidic compartment was visualized by acridine orange (AO) staining, which was performed as described by (Yang et al. 2008). Briefly, Human A549 cells were treated with 0 or 10 μM arsenite for 24 h and stained with 1 μg/ml acridine orange in serum-free medium at room temperature for 15 min. Then the cells were washed twice, each for 5 min and immediately visualized under a fluorescent microscope.

Western blot assay

To determine the relative protein expression, total proteins were extracted and analyzed by the Immune blot assay. Cells were harvested following indicated time exposure to various concentrations of arsenite. The lysates were sonicated and centrifuged for 5 minutes at 10,000x g and supernatant fractions were stored at – 80°C or used immediately. The total protein extracts were separated by 6% - 12% SDS-PAGE gel and Immuneblot analysis was performed according to the manufacturer’s instruction (Cell signaling, USA), after electro-transferring, membrane was blocked in TBS/0.1% Tween 20 with 5% (w/v) nonfat dry milk for 1 hour at room temperature, then incubated with primary polyclonal antibodies overnight at 4°C. After washing with TBS/0.1% Tween 20, target protein band, specifically bound to the primary antibody, was detected by LI-COR (LI-COR Odyssey, USA) system with IRDye® 800CW-conjugated secondary antibody. Western blot bands were quantified by densitometry relative to the GAPDH loading control using image software.

Quantitative real-time polymerase chain reaction analysis for gene expression

Total RNAs were extracted by using the RNaseasy Mini Kit for PARP and caspase3-mRNA analyses according to the manufacturer’s instructions. The primers of mRNA PARP, Caspase3 and GAPDH were used for RT-PCR. The PCRs were performed in the Bio-Rad CFX96™ sequence detection system (Bio-Rad, Hercules, CA, USA), in accordance with the manufacturer’s instructions. Expression of mRNA was performed in two steps using miScript II RT Kit and miScript SYBR Green PCR Kit (Qiagen, USA). The Caspase3 and PARP mRNA levels were normalized to GAPDH mRNA levels, which were determined in the same tube as the target gene (Caspase3 and PARP). For quality control, distilled water was used as negative controls. First strand cDNA from RNA templates was performed using miScript II RT Kit according to manufacturer’s protocol. After reverse transcription reaction, real-time PCR was performed by a Bio-Rad CFX96™ sequence detection system using Quantitect SYBR Green PCR Master Mix (Qiagen, USA). Real-time
PCR amplification conditions were 50°C for 2 min, 95°C for 15 min, followed by 40 cycles at 94°C for 15 s, 55°C for 30 s, and 70°C for 30 s. Melting curve at 60°C for 1 min. Melting curve analysis of the PCR products confirmed the absence of secondary products. All real-time PCR assays were performed in triplicate. Quantification of each analyze expression compared with untreated controls was assessed using the 2^(-ΔΔCT) method. Fluorescence data were processed and analyzed.

Statistical analysis

All experiments were repeated at least three times. The data were expressed as means ± SD (standard deviation). Intergroup differences were tested by analysis of variance (One Way ANOVA), followed by Tukey’s test. The software used was Excel and SPSS, version 13.0 (SPSS Inc., Chicago, IL, USA). Values of p < 0.05 were considered statistically significant (indicated in tables and figures as *).

Results

When A549 cells were treated with increasing concentration of NaAsO₂ for 24 hours (blue columns in Figure 1), cell viability remained largely intact until concentration exceeded 20.0 μM. At the highest concentration of NaAsO₂ employed (80.0 μM), cell viability decreased to about 70%. However, as exposure time increased to 48 hrs, the effect of NaAsO₂ treatment on cell viability was more pronounced. For example, cell viability was reduced to 85% at a low concentration of 5.00μM. As concentration goes up, cell viability steadily decreased to 50% when NaAsO₂ concentration reached 80.0 μM.

To confirm the ROS (reactive oxygen species, or superoxide and hydrogen peroxide) production induced in A549 cells, ROS levels were detected by fluorescence microplate reader at different concentration arsenite exposure. The results showed that ROS production is sensitive to arsenite exposure and the ROS significant release at 0.625 μM and at dose and time-dependent manner (Figure 4). For further confirmation the relationship between cytotoxicity and the arsenite via ROS production, a scavenger of ROS, NAC was added. The antioxidant activity of NAC is thought to be due to the thiol containing motif which acts as a precursor for GSH synthesis[16,17]. The data shown that the cell toxicity caused by arsenite significantly decreased with adding NAC (Figure 5).
Another indication of autophagy occurrence in cells is the change of the expression ratio of LC3-II to LC3-I. Autophagy increases the ratio of LC3-II to LC3-I due to increased conversion of LC3-I to LC3-II. As shown in Figure 4, the ratio of LC3-II to LC3-I steadily went up as NaAsO₂ concentration is increased from 0 to 40 μM, providing additional evidence of autophagy occurring after exposure to NaAsO₂.

The lung epithelial cells treated with NaAsO₂ showed increased expression of active caspase-3 and PARP, two hallmark proteins of apoptosis. Results shown in Figure 5 confirmed that the active 19kDa cleaved caspase-3 and 89kDa cleaved PARP were increasingly expressed in cells exposed to progressively higher NaAsO₂ concentrations. Such changes are also occurring at the mRNA level, as verified by real-time PCR assays of mRNA expression of PARP and caspase-3 (Figure 6).

Discussion

Autophagy is the catabolic mechanism involving cell degradation of unnecessary or dysfunctional cellular components through the lysosomal machinery. Autophagy can be a survival mechanism but can also be a pathway for cell death. The synthesis, degradation and renewal of cellular components are critical to cell survival. Autophagy, a cellular mechanism associated with the degradation of unnecessary or dysfunctional organelles plays a vital role in maintaining homeostasis in a cell. When a cell is under tolerable stress conditions, autophagy may serve as a repair mechanism and return the cell back to its normal state. However, if a cell is subjected to severe or continuous stress conditions, autophagy may trigger apoptosis, or cell death. During the process of autophagy, autolysosomes are formed when lysosomes fuse with autophagosomes that have engulfed degraded cellular components in the cytoplasm. As the cellular components are digested, the pH level within the capsule becomes more acidic. The method of AO staining helps us to visualize autophagy by making these cellular acidic vessels appear an orange-red color. The orange-red stains seen in Figure 3b shows that the A549 cells treated with 10.0 μM of NaAsO₂ for 24 h clearly underwent autophagy. However, the occurrence of apoptosis cannot be concluded from AO staining results.

During autophagy, a cytosomal protein LC3-I is conjugated to LC3-II. Figure 4 shows that as concentrations of NaAsO₂ increase, so does the ratio of LC3-II to LC3-I, further supporting that autophagy has occurred. On its own, Figure 4 does not present any evidence of apoptosis.

Figure 1 and Table 1 indicate that cell viability increases at exposure to 5 μM of NaAsO₂ (24h). Coupled with the results of Figure 4, this could be evidence that exposure to low concentrations of NaAsO₂ for 24 hours can initiate in A549 cells an autophagic response promoting cell survival. Exposure to NaAsO₂ at increasing concentrations for more extensive periods of time leads to apoptosis, clearly indicated by the significant loss of cell viability shown in Figure 1 (48h) and Table 1 (48h). Further study is needed to clarify if it was autophagy that contributed to cell death in A549 cells at all other exposure levels to NaAsO₂.

Activation of Caspase3 initiates a cell’s entry into the apoptotic signaling pathway. Once activated, Caspase-3 cleaves nuclear proteins such as PARP, setting the cell on a course of destruction. PARP is involved in repairing damaged DNA, but once it is cleaved it is no longer active and DNA cannot be repaired. The destruction of DNA within the nucleus is a hallmark feature of apoptosis. Evidence that apoptosis is occurring is supported by the increased expression of the activated Caspase-3 and inactivated PARP as seen in Figure 5 and Figure 6.

Our study supports that NaAsO₂ induces autophagy and apoptosis in A549 cells. In this study, we found that in vitro exposure of A549 cells to high concentrations of NaAsO₂ results in apoptosis. Further study is needed to clarify if autophagy contributed to cell death at these high exposure levels to NaAsO₂. At lower concentrations, NaAsO₂ induced autophagy in A549 cells but apoptosis could not be detected.

Figure 1: Western Blot analysis demonstrates increased ratio of LC3-II to LC3-I as NaAsO₂ exposure induces the conversion of LC3-I to LC3-II (treatment of 24 hrs). No apoptosis marker can be detected within this concentration range.
Programmed Cell Death of Cultured A549

Table 1: Cell viability (%) of A549 cells after exposure to different concentrations (μM) of sodium arsenite for 24 hours and 48 hours.

| Treatment | 0 μM | 1.25 μM | 2.5 μM | 5 μM | 10 μM | 20 μM | 40 μM | 80 μM |
|-----------|------|---------|--------|------|-------|-------|-------|-------|
| 24 hr     | 100% | 103%    | 103%   | 113% | 86.0% | 99.8% | 80.0% | 71.8% |
| 48 hr     | 100% | 80.4%   | 102%   | 88.0%| 83.4% | 81.7% | 85.4% | 50.4% |

Figure 7: Detection of active caspase-3 and PARP in A549 cells exposed to NaAsO₂ for 24 hrs by Western Blotting.

Figure 8: Real-time PCR assay for mRNA expression of PARP and Caspase-3 after treatment with NaAsO₂ for 24 hrs. Data presented in triplets (*p < 0.05 versus control).

Long-term consumption of arsenic contaminated water may result in accumulation of toxic levels of arsenic in the bloodstream which may ultimately build up in the lungs through blood circulation and lead to serious damaging health effects. This is a major worldwide concern, especially in third-world countries where water treatment is not affordable and in the western United States where public and domestic wells have shown increased levels of arsenic.
