QUALITY OF ‘TAHITI’ ACID LIME FERTILIZED WITH NITROGEN AND POTASSIUM IN THE SEMIARID REGION OF MINAS GERAIS

ARIANE CASTRICINI, JOSÉ TADEU ALVES DA SILVA, INÊZ PEREIRA DA SILVA, MARIA GERALDA VILELA RODRIGUES

ABSTRACT - This study aimed to evaluate external characteristics and juice obtained from ‘Tahiti’ acid lime produced under nitrogen and potassium fertilization. This study had a completely randomized design with three replicates of four fruits of the two central plants, 4 x 5 factorial and four N doses (0, 25, 50 and 100 Kg ha⁻¹ year⁻¹) and five K₂O doses (0, 25, 50, 100 and 200 Kg ha⁻¹ year⁻¹), totaling 20 treatments. In the postharvest period, external characteristics (size, color and skin thickness, firmness and fresh mass) and juice (content, percentage, soluble solids, technological index, pH, titratable acidity, ratio and ascorbic acid) of fruits were evaluated. Size, skin color, soluble solids content and pH of ‘Tahiti’ acid lime juice were not affected by N and K₂O fertilization. Skin thickness, juice percentage and technological index increased with the N and K₂O doses applied to the soil. Juice content and fruit firmness decreased with application of K₂O doses. Titratable acidity and ascorbic acid content increased with the K₂O doses. The different nitrogen and potassium doses influenced more the juice quality than the external characteristics of ‘Tahiti’ acid lime in the postharvest period.

Index Terms: Citrus latifolia Tanaka, postharvest, size, color, juice.

QUALIDADE DE LIMA ÁCIDA ‘TAHITI’ ADUBADA COM NITROGÊNIO E POTÁSSIO NO SEMIÁRIDO DE MINAS GERAIS

RESUMO - Objetivou-se avaliar as características externas e as do suco de lima-ácida ‘Tahiti’, produzida sob adubação nitrogenada e potássica. Utilizou-se o delineamento inteiramente casualizado, com três repetições de quatro frutos das duas plantas centrais, em esquema fatorial 4 x 5, sendo quatro doses de N (0; 25; 50 e 100 Kg ha⁻¹ ano⁻¹) e cinco doses de K₂O (0; 25; 50; 100 e 200 kg ha⁻¹ ano⁻¹), totalizando 20 tratamentos. Em pós-colheita, avaliaram-se as características externas (tamanho, cor e espessura da casca, firmeza e massa fresca) e as do suco (volume, percentagem, sólidos solúveis, índice tecnológico, pH, acidez titulável, ratio e ácido ascórbico dos frutos). O tamanho, a cor da casca, o teor de sólidos solúveis e o pH do suco de lima ácida ‘Tahiti’ não foram influenciados pelas adubações com N e K₂O. A espessura da casca, a porcentagem de suco e o índice tecnológico aumentaram com as doses de N e K₂O aplicadas no solo. O volume de suco e a firmeza do fruto reduziram com as aplicações dos doses de K₂O. A acidez titulável e o teor de ácido ascórbico aumentaram com as doses de K₂O. As diferentes doses de adubação nitrogenada e potássica influenciaram mais na qualidade do suco que nas características externas de lima-ácida ‘Tahiti’, em pós-colheita.

Termos para Indexação: Citrus latifolia Tanaka, pós-colheita, tamanho, cor, suco.
INTRODUCTION

The northern region of Minas Gerais accounts for 52.6% of the state’s ‘Tahiti’ acid lime (Citrus latifolia Tanaka) production. In the Irrigated Perimeter of semiarid Jaíba, ‘Tahiti’ acid lime is the second most important agricultural activity, with a total planted area of 1,500 ha, with production of 42,000 tons (IBGE, 2012). The region has characteristics for the development of citrus, such as low incidence of pests and diseases, rainfall around 800 mm/year and climatic conditions that, together with irrigation, allow the flowering of ‘Tahiti’ acid lime tree throughout the year (AZEVEDO et al., 2010).

According to Silva (2015) in Brazil, there are few scientific publications on ‘Tahiti’ lemon fertilization, mainly with N and K₂O. Fertilization recommendations currently made for this crop are mostly based on data obtained from research on orange crop, which is the most studied citrus plant, mainly on fertilization and nutrition.

The quality of fruits demands special care in crop fertilization. According to Aular and Natale (2013), there is no single behavior for the effects of nutrients on quality. The soil and climatic conditions, the cultivar and the nutrient dose are determinant. Maximum production and the best quality of fruits also depend on the balance among nutrients. Thus, the proportion of elements in the plant tissue plays a more important role than the absolute content of each nutrient.

According to Quaggio et al. (2006) and Mattos Júnior et al. (2014), both the lack and excess of N directly interfere in the size and quality of fruits because high N doses tend to increase the number of fruits per plant to the detriment of their size, which can be a disadvantage for the fresh fruit market.

High K₂O doses increase the fruit size and skin thickness, which are desired for the fresh fruit market. However, plants with high K supply tend to produce fruits with higher acidity and lower soluble solids content, depreciating them for the juice processing industry (ALVA et al., 2006; QUAGGIO et al. 2006).

Citrus juice processing industries consider physical and chemical parameters such as acidity, pH, ratio, soluble solids, ascorbic acid, essential oil, color and viscosity not only to control the quality of the product, but also to meet the requirements established by the consumer market (PACHECO et al., 2014). However, in the recent literature, no studies correlating fertilization with most of the physical and chemical parameters studied in post-harvest are found.

For classification of ‘Tahiti’ acid lime according to Ceagesp standards, skin color, size and defects (severe, mild and spots) are taken into account. The quality standards used for export are: rough skin, bright olive green color and diameter of the equatorial region between 47 and 65 mm. However, according to Nascimento and Santos (2013), the lack of fruit quality, especially in relation to the rapid loss of skin color, which tends to yellowing after harvesting, limits the opening of new international markets for Brazilian producers of this cultivar.

The study of the post-harvest quality of ‘Tahiti’ acid lime as a function of fertilization, together with the phytotechnical responses, could guide the management of soil fertility and mineral nutrition of plants in the irrigated perimeter of Jaíba. Therefore, the aim of this study was to evaluate the external characteristics and juice of ‘Tahiti’ acid lime produced under nitrogen and potassium fertilization.

MATERIAL AND METHODS

The experiment was conducted in four harvest seasons, in 2009, 2010, 2011 and 2012, in the municipality of Jaíba, located in the semiarid region of northern Minas Gerais, Brazil. The geographic coordinates are: 15º 48’ 09” S, 43º 18” 32’ W, 533 m a.s.l. and average annual rainfall of 800 mm, average temperature of 25 ºC and 56% relative humidity. The soil of the experimental area is classified as Typic Quartzipsamment and had the following characteristics in the 0 to 0.20 m layer: pH (in H₂O) = 6.6; Al exchangeable (cmolc dm⁻³) = 0.0; H + Al (cmolc dm⁻³) = 1.1; Ca = (cmolc dm⁻³) = 1.6 and Mg (cmolc dm⁻³) = 0.6; P-Mehlich 1 (mg dm⁻³) = 8.7; K-Mehlich 1 (mg dm⁻³) = 29.5; Organic matter = 6.0 g kg⁻¹; Sand = 85 g kg⁻¹; Clay = 10 g kg⁻¹ and Silt = 5 g kg⁻¹.

The work was carried out in a twelve-month-old ‘Tahiti’ (Citrus latifolia Tanaka) orchard grafted on ‘Cravo’ lemon tree (Citrus limonia L. Osbeck). The planting of seedlings was carried out in pits with dimensions of 0.40 x 0.40 x 0.40 m and spacing of 8 m between rows and 5 m between plants. Fertilization was carried out with applications of 120 g of P₂O₅ and 15 liters of bovine manure in the pit. Phosphate fertilization was applied once a year according to soil analysis, as recommended by the Fertilizer and Liming Group of São Paulo for citrus (1994). Simple superphosphate was used as a source of phosphorus. Micronutrients were applied four months after planting using 50g of FTE BR-12...
QUALITY OF ‘TAHITI’ ACID LIME FERTILIZED WITH NITROGEN AND POTASSIUM....

RESULTS AND DISCUSSION

All external and juice data evaluated showed normal distribution, with calculated values being lower than the table values (0, 114), for p = 0.05. There was no significant interaction between N and K₂O doses for the external and juice variables for ‘Tahiti’ acid lime.

Length, diameter, fresh mass, soluble solids content, fruit pH, and L* and C* parameters of skin color were not influenced by the individual effects of N and K₂O fertilizations. The mean values, regardless of doses of fertilizers, were: fruits with 56.32 mm and 52.56 mm in length and diameter, respectively,
fresh mass of 86.15 g, skin with luminosity (L*) of 48.40 and chroma (C*) of 39.02, soluble solids of 9, 10 ° Brix and pH 2.23.

Fruits presented size (length and diameter) that meets the fresh fruit market demand, because according to Luchetti et al. (2003), fruits with size of approximate 55 to 70 mm in length and 47 to 65 mm in diameter are preferred by the fresh fruit market.

The hue angle was influenced by the effect of N doses, while firmness and juice volume were affected by K2O doses. There was a reduction in the hue angle with increased nitrogen fertilization until approximately 300 g plant−1 year−1. From this dose, a slight increase in the angle is observed, that is, the green skin color became more intense (Figure 1A). Despite the reduction, the values are within the range of green tonality, which is desirable for the commercialization of ‘Tahiti’ acid lime. N is an essential element, structural component of proteins, chlorophyll and nucleic acids and influences fruit quality, because its deficiency affects fruit production and size, which present thin skin, pale green color and early maturation (MAGALHÃES, 2006).

The maintenance of the dark green color of ‘Tahiti’ lime skin is desirable during its post-harvest life, while total or partial yellow coloration prevents its acceptance by the consumer (TAVARES et al., 2004). According to Bassan et al. (2016), fruits under marketing conditions are turgid, with green bark, without rotting and physiological disturbances. Mattos Junior et al. (2010) verified that the N content in the leaf of ‘Tahiti’ acid lime was positively correlated with the green color of the fruit skin, that is, the higher leaf N content of fruits, the more intense their green color.

Increasing K2O doses reduced fruit firmness and juice volume (Figure 1B and C, respectively). The firmness of ‘Fuji’ apple pulp also reduced with increasing K2O doses and their excess may favor the appearance of physiological disturbances and limit the longevity of these fruits, as they decrease pulp firmness (HUNSCHÉ et al. 2013). According to Souza et al. (2013), firmness of apples decreased in response to high K2O doses in a Cambisol, regardless of N doses.

According to Pacheco et al. (2014), fruits with low firmness present less resistance to transportation, storage and handling and are therefore rejected by consumers. Although K was considered an “element of quality”, under the conditions of the present work, the use of increasing K2O doses reduced fruit firmness.

Quadratic regression was best adjusted for the tendency of skin thickness of ‘Tahiti’ acid lime as a function of the N (Figure 2A) and K2O doses (Figure 2B). N and K2O doses that provided maximum skin thickness were 59 and 140 kg ha−1 year−1 of N and K2O, respectively. According to Alva et al. (2006), high K2O doses cause increased fruit size and skin thickness, which are desirable qualities for the fresh fruit market; however, plants with high K supply tend to produce fruits with higher acidity and lower content of solids, which depreciates fruits for the juice industry.

K is the nutrient responsible for the maintenance of turgor and extensibility of cells, affecting fruit size. Studies have shown that K increases fruit size and skin thickness, which are characteristics favorable to the fresh fruit market. However, larger fruits with thicker skin may have lower juice yield and lower soluble solids contents, which are undesirable for the production of concentrated juice (MATTOS Jr.; QUAGGIO; CANTARELLA, 2005).

Juice percentage, expressed as a function of fruit size, linearly increased with N (from 66% to 69%) (Figure 3A) and K2O doses (from 53% to 95%) (Figure 3B). According to Pacheco et al. (2014), juice yield around 54% is desired by both fresh fruit market and the juice processing industry. In the present work, both N and K2O doses provided juice yield over 50%.

In order to obtain the juice percentage, fruit mass was considered in the denominator of the equation; however, there was no significant difference for fresh fruit mass as a function of fertilization. It is suggested, therefore, that the N and K2O doses influenced not only the juice mass gain, but also the other factors involved in the fruit filling process, such as number of vesicles containing the juice or “bagasse”. Mendonça et al. (2006) evaluated the yield of ‘Tahiti’ acid lime fractions, among which, the juice percentage was 50.1% in relation to the other fractions studied. In the present work, the increase in the juice percentage with maintenance of fruit mass suggests variations in the other fruit fractions as a function of fertilization.

Linear regression was the best fit between N (Figure 3C) and K2O fertilization (Figure 3D) and technological indexes. The calculation of this quality indicator considered soluble solids content that was not influenced by N and K2O fertilizations, and juice % that increased proportionally to the increase in N and K2O doses. The technological index is not the result of a measurement, but rather a calculation, which parameters are the soluble solids content and the juice yield; being influenced by all factors affecting the trend of these parameters, such as climatic conditions, irrigation and fertilization...
In the industry, fruits with the highest industrial yield indexes are the most desirable. Quality indexes relating solid soluble contents and industrial yields are already used for the differentiated payment of citrus and passion fruits, and this trend has been adopted by agroindustries. Nitrogen fertilization did not influence the titratable acidity of the acid file, which presented an average value of 5.3% in the different N doses. The regression that best fit between K$_2$O doses and titratable acidity was the quadratic one (Figure 4A), where maximum acidity (5.7%) was obtained with K$_2$O application of 124 kg ha$^{-1}$ year$^{-1}$. The increase in titratable acidity with K$_2$O doses can be attributed to the higher concentration of organic acids in the juice due to the reduction in the juice volume with increased potassium fertilization (Figure 1C). Unlike titratable acidity, ratio decreased with K$_2$O doses (Figure 4B). This variable is calculated by the solid soluble / titratable acidity ratio, since there was no effect of fertilizations on soluble solids content, and acidity increased proportionally to the potassium fertilization, the ratio reduced with increasing K$_2$O doses.

Almeida and Baumgartner (2002) found that higher K$_2$O dose (150 kg ha$^{-1}$), compared to the others, caused an increase in the acidity of ‘Valencia’ orange juice only within the lowest N dose (94 kg ha$^{-1}$ of N), while intermediate K$_2$O dose (75 kg ha$^{-1}$) caused a decrease in the soluble solids content, only within the highest N dose. The effect of K$_2$O doses on juice acidification is consistent with literature (ALVA et al., 2006; QUAGGIO et al., 2006).

Quadratic regression was the best fit between ascorbic acid content and K$_2$O doses (Figure 4C) and there was no significant effect of N on this variable. The maximum ascorbic acid content (62.5 mg ascorbic acid / 100 ml juice) was obtained with K$_2$O dose of 100 kg ha$^{-1}$ year$^{-1}$. Bernardi et al. (2007) also verified quadratic response of ascorbic acid values of tomatoes in relation to K$_2$O doses applied in fertilization; and according to the authors, K supply has a positive effect on the ascorbic acid concentration due to the increased availability of the nutrient.

\[ y = 120.58 + 0.0004x - 0.0000007x^2 \quad R^2 = 0.974 \]

\[ y = 54.4 - 0.0244x \quad R^2 = 0.915 \]

CONCLUSIONS

Size, skin color, soluble solids content and pH of ‘Tahiti’ acid lime juice were not influenced by N and K₂O fertilizations.

Skin thickness, juice percentage and technological index increased with N and K₂O applied to the soil.

Juice volume and fruit firmness reduced with applications of K₂O doses.

Titratable acidity and ascorbic acid content increased with K₂O doses.
