Middle cerebral artery · Sphenoidal segment · Main trunk · M1 segment · Middle cerebral artery classification

Abstract
Objective: The middle cerebral artery (MCA) is the most commonly treated artery in mechanical thrombectomy stroke trials; however, there is no pragmatic agreement about the segmental anatomy and nomenclature utilized. It results in significant clinical-radiological dissociation and introduces bias in research trials. The purpose of the study is to review and compare angiographic anatomy with microsurgical anatomy literature of the MCA with emphasis on the discrepancy. Methodology: Consecutive cerebral angiograms between January 2011 and March 2014 were retrospectively reviewed by endovascular surgical neuroradiologists. Information about the anatomy of the sphenoidal segment of the MCA classified as classic and non-classic pattern, the lenticulostriate artery takeoff pattern, and the course angulation of the sphenoidal segment were studied. Results: A total of 500 patients, 886 cerebral angiograms, were reviewed. We found the classic pattern of the main trunk MCA bifurcation and a straight angulation course in less than half of the cases. The lenticulostriate arteries arose not...
Introduction

The middle cerebral artery (MCA) is the most commonly treated cerebral artery using mechanical thrombectomy [1]. Indeed, robust data on recanalization rates using stent retrievers was obtained from well-designed trials focused on the MCA recanalization. Despite the fact that the MCA has been the subject of comprehensive research, there is no consensus about the anatomy and nomenclature utilized to describe the site of occlusion within the MCA [2–4].

In 1938, Fischer [2] originally named the sphenoidal segment as the M1 segment. The M1 segment, horizontal in its course, could or could not include the main bifurcation of the MCA; in such case, a pre-bifurcation and post-bifurcation M1 segment would be present. At the genu, and coinciding with a change in plane, the insular segment initiates its vertical course and classically described as genu includes the origin of the main MCA divisions. More recently, and with the advent of acute endovascular treatment for ischemic stroke, in most instances it has arbitrarily been assigned as follows: the main MCA trunk as the M1 segment and the main MCA divisions as the M2 segments [5]. It is widely presumed about the MCA anatomy that the horizontal segment is straight, its major MCA bifurcation occurs at the genu, and bifurcation also typically occurs distal to the lenticulostriate arteries (LSAs) takeoff [3]. However large anatomical studies addressing this issue are lacking and most of them are based on small cadaveric series.

Our purpose is to evaluate, based on angiography, the frequency of the anatomical variations of the sphenoidal segment according to the site of the main MCA bifurcation, the origin of the LSAs, and the sphenoidal segment course pattern.

Methods

Consecutive patients undergoing cerebral angiography for different reasons between January 2011 and March 2014 were selected for the study. We included patients undergoing cerebral angiography without any known mass effect on brain imaging (head computed tomography scan and/or brain magnetic resonance imaging) or other notable intracranial pathology such as intracranial aneurysms, dissections, stenosis, vasculitis, arteriovenous malformations, or any lesion that could distort the normal architecture and integrity of the vessels for the purpose of precise visualization of the MCA vascular anatomy.

Angiographic examinations were performed using a commercially available biplanar angiographic unit (Integris Allura; Philips Medical Systems, Best, the Netherlands). Standard anteroposterior (AP) and lateral cerebral angiograms were selected from the integration of Picture Archiving and Communication Systems (PACS) program by one of the authors (M.A.Q) and were verified by three experienced endovascular surgical neuroradiologists (G.J.R., A.M., R.K.) and classified using previously described landmarks as follows.

Angiographic Sylvian Point

The point of bifurcation of the sphenoidal segment was noted by drawing a perpendicular line from the angiographic Sylvian point (ASP). The ASP is defined as the point where the last main branch, which is usually the angular branch of the MCA, leaves the posterior end of the insula, turning inferolaterally to reach the surface of the brain. This point approximates the apex of the insula and represents the posterior limit of the Sylvian fissure. The ASP normally lies 30 to 43 mm from the inner table of the skull on a routine AP view and is located at the halfway point on the clinoparietal line (points a, b) [6], as shown in Figure 1.
The Classic and Non-Classic MCA Bifurcation

We classified the main MCA bifurcation as “classic” when the bifurcation occurred at the genu or junction between the horizontal and vertical segments (Fig. 2a), and as “non-classic” when the bifurcation occurred before the genu and therefore within the horizontal segment (Fig. 2b). “Early bifurcation” was defined as the bifurcation occurring within 10 mm from the origin of the sphenoidal segment or the terminal internal
carotid artery (ICA) (Fig. 2c). The anterior temporal artery, regardless of its size, was not considered to determine the main MCA bifurcation pattern. The length of the main MCA trunk was measured, which is the distance from the origin of the MCA at the terminus ICA to the main MCA bifurcation.

**Sphenoidal Segment Course**

Angular variations of the sphenoidal segment were analyzed and classified into five groups as previously described [7]: (1) oblique descent; (2) convexity downwards; (3) straight; (4) oblique course dorsad; and (5) convexity dorsad (Fig. 3a–e). Furthermore, they were categorized according to the age groups.

**Lenticulostriate Arteries**

The takeoff of the LSAs was classified as pre- and/or post-bifurcation of the main MCA (main MCA trunk and/or MCA divisions, including the horizontal and/or vertical course of the divisions).

Furthermore, the anatomic similitude (mirroring) between the right and left MCA segments were studied in those patients with bilateral cerebral angiograms.

**Results**

A total of 500 patients were included for the study period that provided a total of 886 cerebral angiograms that were reviewed. Out of these, 386 patients had bilateral cerebral angiograms, and the remaining had unilateral cerebral angiograms, 55 on the left side and 59

**Fig. 3. a–e** Angular variation of the sphenoidal segment. a Oblique descent. b Convexity downwards. c Straight. d Oblique course dorsad. e Convexity dorsad.
on the right side. There were 241 males and 259 females with a mean age of 55.6 years (range 12–94).

**Bifurcation Site, Length, and Mirror Pattern of the Sphenoidal Segment**

The main MCA trunk bifurcation occurred along the horizontal segment and proximal to the genu (non-classic) in over 50% of all cases, and early bifurcation was noted in a quarter of these cases (Table 1).

The mean length of the main MCA trunk was 17.06 mm (±3.84) in the classic pattern compared to 10.33 mm (±3.31) in the non-classic pattern (Table 1).

The mirror pattern of the main MCA bifurcation was analyzed in those 386 patients who had bilateral cerebral angiograms, and a mirror pattern was observed in less than half of the patients (159 patients, 41.2%). The frequency was as follows: classic pattern (95 patients, 44.2 %), non-classic pattern without early bifurcation (28 patients, 24%), and non-classic pattern with early bifurcation (36 patients, 32%).

**Sphenoidal Course Angulation**

The most common course angulation pattern found was Straight, accounting for 429 cases (48.4%), followed by oblique descent, found in 234 cases (26.4%). Convexity downwards, oblique course dorsad, and convexity dorsad were found in 99 cases (11.8%), 90 (10.2%), and 17 (3.8%), respectively (Table 2).

Two-thirds of the total sample were found to have either a straight or an oblique descend course. We further studied the course angulation according to the patients’ age, dividing them into three age groups: <20 years, 21–50 years, and >50 years (Table 3). The mirror pattern was noted again only in a minority of patients (15–34%) with the highest incidence in the

| 4 Oblique course dorsad | 90 (10.2%)                        | 47 (10.6%)                         | 43 (9.8%)                         |
| 5 Convexity dorsad | 32 (3.6%)                         | 17 (3.8%)                          | 15 (3.4%)                         |
oblique descent course pattern. A point biserial correlation analysis was performed to
determine the correlation between age and the sphenoidal segment being straight (less
frequently straight with age). We found a negative correlation that was statistically signif-
icant; as the patient ages, the sphenoidal segment becomes less frequently straight ($r$ = –0.07,
$p$ value = 0.02).

**LSA Takeoff**

Among the MCAs with classic bifurcation, the LSAs originated from the main trunk prior
to its bifurcation in 265 cases (62.6%); however, in the remaining 158 cases (37.4%), the
LSAs originated from both, the main MCA trunk and main MCA divisions. In the MCAs with
non-classic non-early bifurcation, the LSAs emerged from the main trunk only in 91 cases
(38.4%) and from both main trunk and main MCA divisions in 146 cases (61.6%). As expected,
in the MCAs with early bifurcation, the LSAs originated from the main MCA and main MCA
divisions in most cases (200, 88.4%), and in 26 (11.6%) it originated from the main MCA
trunk. When combined all together, the LSAs emerged from the main MCA trunk in 382 cases
(43.2%) and from the main MCA trunk and main MCA division in 504 cases (56.8%) (Table 4).

**Discussion**

Contrary to the common knowledge in our studied population, we found that <50% of
the cases had a main MCA trunk bifurcation at the genu, in <50% the horizontal segment was
straight, and <50% had the takeoff of the LSAs from the main MCA trunk. Conventional
knowledge about the sphenoidal segment often highlights three main points. One, the sphen-
oidal segment, classically referred to as the M1 [1, 2, 4, 8]. Two, the course angulation of the

Values are presented as $n$ (%).
sphenoidal segment is usually straight running parallel to the sphenoidal ridge [3]. Three, the LSAs arise from the main MCA trunk [5].

Our findings about the MCA anatomy have confirmed prior cadaveric studies. Gibo et al. [3] reported the major bifurcation proximal to the genu in 86% of the studied hemispheres. Similar findings were noted by another study that examined 50 cerebral hemispheres, finding the bifurcation proximal to genu in 82% of the hemispheres, at the level of the genu in 8%, and distal to the genu in 10% of the hemispheres [9]. On the other hand, Türe et al. [4] examined 20 human cadavers (40 cerebral hemispheres) and reported that the main bifurcation of the MCA occurred at the genu in 57.5% of the cerebral hemispheres; interestingly, 27.5% had the main bifurcation 4–10 mm distal to the genu, and in 15% the bifurcation occurred 5–8 mm proximal to the genu. Another important finding in our study and worth emphasizing was the change in the angulation course with age, being less frequently straight with aging. Our findings were similar to those observed by Krayenbühl et al. They found that the sphenoidal segment extends obliquely lateral and superiorly in children and juveniles compared to the older population in whom the artery runs obliquely lateral and downward. This could be explained by the increased tortuosity in the older population [7]. Vuillier et al. [10] assessed the course and divisional pattern of the sphenoidal segment of the MCA with the help of transcranial color-coded sonography in 50 patients < 55 years of age. In their study, the sphenoidal segment ran straight in 52% of the cases. In the remaining 48%, the segmental course was either anteriorly curved (19%) or posteriorly curved (29%). This is of importance during mechanical thrombectomy in patients with acute ischemic stroke as this aged population is the most commonly treated age group for ischemic stroke. A strongly curved sphenoidal segment of the MCA has been associated with significantly less successful recanalization compared to when the sphenoidal segment is straight [11, 12]. In a prospective study, the authors studied the vessel branching and curvature in determining the success of recanalization based on indirect magnetic resonance imaging findings. They have concluded that a clot can assume the shape of the curved and tortuous MCA, making its retrieval difficult compared to a straight sphenoidal segment in which mechanical forces when exerted on the thrombus are more successful [11]. Schwaiger et al. [12], in their retrospective analysis, have reported that vessel anatomy, especially the curvature of the carotid terminus and increased angle between the M1 and M2, significantly affected the results of mechanical thrombectomy using a stent retriever. The patients who had unsuccessful recanalization (TICI 0–2a) had larger ICA/M1 and M1/M2 angles in the proximal vessel occlusion and significantly larger M1/M2 angles in distal vessel occlusions. Zurada et al. [13] also reported that the course of the sphenoidal segment was only slightly curved, but the variation and tortuosity could still lead to difficulty in relation to catheterization and embolization procedures.

Operators performing mechanical thrombectomy should be aware that it is quite common for the sphenoidal segment angulation to be present, and it may affect recanalization success rate. In addition, blind microwire navigation of the wire through the thrombus should be done carefully and not confuse the course of the microwire in the subarachnoid space in case of vessel perforation with different angulations. Microcatheter injection may be helpful in ensuring that the microcatheter tip is in the true lumen.

The LSAs are terminal branches that typically supply blood to the basal ganglia and its vicinity, and their occlusion results in the infarction of these structures [14, 15]. In our study, we observed the LSAs arising from the main trunk of the sphenoidal segment prior to bifurcation in 43.2% of the MCAs. In rest of the cases, they arose both from the main trunk and divisional trunk (56.8%) with a much higher prevalence in early bifurcation (88.4%). Table 5 summarizes LSA origin in neurosurgical anatomical studies and suggests that these arteries arise in the main MCA segment prior to its bifurcation in most cases (53–79%). However, in the remaining cases, these also arise from the post-bifurcation segment, which would be
consistent with our observations. It has previously been recommended that the M1 segment should be defined as the segment from the terminus ICA to the main MCA bifurcation, and the location of the occlusion should be localized to the proximal half when the LSAs are involved and to the distal half when spared [5].

The current existing nomenclature of the MCA is controversial. There is often discrepancy in the literature between the microsurgical and angiographic anatomy of the MCA (Tables 6, 7). Delion et al. [16] studied the pattern of branching of the main MCA trunk in 20 arteries of 25 cadavers, describing the M1 segment as the sphenoidal segment extending from the ICA bifurcation to the main MCA division, adjacent to the limen insulae, and the M2 as the insular segment extending from the MCA division to the periinsular sulci. However, Umansky et al. [17] studied the proximal segment of the MCA in 70 unfixed brain hemispheres of 35 cadavers, defining the main MCA trunk or M1 segment as the portion from the MCA origin to the main MCA bifurcation. In 1938, Dr. Erich Fischer [2] was the first one to define the M1 and M2 segments. He defined the M1 segment as the horizontal or sphenoidal portion extending from its origin to the genu, and this segment could include the bifurcation giving a pre-bifurcational and post-bifurcational M1 segment. This definition has been followed by others [3, 18]. However, the most commonly accepted definition of the M1 segment is that segment that extends from its origin at the ICA bifurcation running laterally to the limen insulae, the point of bifurcation [1, 2, 4, 8, 16]. Moreover, the majority of neurointerventionalists has utilized in major stroke trials the later definition, assuming that the bifurcation occurs at the genu or limen insulae [5, 19–22].

As most ischemic strokes occur in the MCA distribution, the location of the obstruction determines the clinical outcome. As it is believed that emboli lodge at branching points, the more proximal the site of obstruction the larger the area at risk. Occlusions of the MCA distal to the bifurcation should lead to a lesser vascular territory injury. Typically, the superior division supplies the frontal and parietal regions, while the inferior division supplies the

|                           |                             | Superior or inferior trunk of the M2 segment near the bifurcation: 4%  |
temporal, temporo-occipital, and angular regions [3]. Controversial data exist in this regard, but studies have not been controlled for the division affected, superior versus inferior, and whether the division is dominant [19–22]; yet, they are collectively referred as M2 occlusions. In addition, LSAs may also have variable origin, thereby affecting the outcome depending on their involvement given the lack of collaterals.
Limitations to our study include the retrospective nature of the study and that the data pertain to a single center. However, our study of 500 patients is the largest series specifically emphasizing on the anatomical details of the sphenoidal segment of the MCA.

**Conclusion**

In the era of mechanical embolectomy using retrieval stents for acute embolic occlusion of the proximal segment of the MCA, familiarity with the anatomy and most common anatomical variants of the MCA segments are important. It is imperative to develop an agreement in the nomenclature of MCA occlusions in acute ischemic stroke, to improve our current practice, and to develop future research given the clinical and radiological implications.

**Table 7. MCA sphenoidal segment definition based on the radiological studies in acute ischemic stroke trials**

| First author [ref.], year | M1 segment definition | M2 segment definition |
|---------------------------|-----------------------|-----------------------|
| Saver [19], 2015          | M1 segment of the MCA is defined as the arterial trunk from its origin at the ICA to the first bifurcation or trifurcation into major branches, neglecting the small temporopolar branch | n.a. |
| Jovin [22], 2015          | M1 MCA segment is defined as the first branch of the intracranial ICA that courses horizontally from its branching point off the ICA through the Sylvian fissure up to the first bifurcation distal to the origin of the lenticulostriate arteries in the distal aspect of the Sylvian fissure (limen insulae); large anterior temporal branches arising proximal or at the level of the LSAs are not considered M2 segments, and the remainder of the M1 segment distal to the anterior temporal branch regardless of the size of the latter is still considered M1 segment up to its next bifurcation | |
| Campbell [20], 2015       | Proximal MCI prior to bifurcation | Distal MCA between bifurcation and exit from the Sylvian fissure |
| Goyal [21], 2015          | The segment extends from the origin to the site of bifurcation or trifurcation (the anterior temporal artery is considered a branch of the M1 segment) | This segment extends from the site of bifurcation or trifurcation to the origin of the cortical branches |
