A frequency-constrained geometric Pontryagin maximum principle on matrix Lie groups

Shruti Kotpalliwar, Pradyumna Paruchuri, Karmvir Singh Phogat, Debasish Chatterjee, Ravi Banavar

Abstract—In this article we present a geometric discrete-time Pontryagin maximum principle (PMP) on matrix Lie groups that incorporates frequency constraints on the controls in addition to pointwise constraints on the states and control actions directly at the stage of the problem formulation. This PMP gives first order necessary conditions for optimality, and leads to two-point boundary value problems that may be solved by shooting techniques to arrive at optimal trajectories. We validate our theoretical results with a numerical experiment on the attitude control of a spacecraft on the Lie group SO(3).

I. INTRODUCTION

Most engineering systems are required to operate in a certain pre-defined region of the state and control spaces. For instance, since mechanical systems are inertial, mechanical actuators have natural limitations in terms of, e.g., the torque magnitudes and the operating frequencies. In the control literature these are known as control magnitude and frequency constraints, respectively. Control magnitudes must be limited, for instance, to prevent rapid movements of robotic arms for safety considerations [1]. Frequency constraints arise from a more subtle consideration. Consider, for instance, read/write operations in disk drives [2] where excitation of the actuator at flexible modes may result in erroneous read/write operations, attitude orientation manoeuvres of satellites fitted with flexible structures such as solar panels [3] may excite the natural frequencies of the flexible structures, leading to vibrations and structural damage unless the natural frequencies are avoided, etc. It is, therefore, desirable to eliminate certain frequencies from the spectra of the control functions of controlled systems at the control synthesis stage.

Traditional attempts by control engineers to handle frequency constraints includes filtering of the actuating signal after control synthesis, or techniques of more recent vintage such as $H_{\infty}$ control [4] that minimize a weighted combination of transfer functions in certain frequencies as part of the synthesis technique. Both these techniques suffer from their own problems: The former is ad hoc and based on the designer’s intuition of the system and actuator, and the latter, though more systematic and incorporates penalties on the frequencies in an interval, still suffers from the inability to completely suppress a pre-specified set of frequencies. More importantly, none of these techniques is capable of incorporating hard bounds on the control actions and the states. Constraints on the control actions and the states are present in the classical optimal control paradigm [5], but frequency constraints in the same framework have not been treated in the literature so far, with the exception of [6], where we presented a set of first order necessary conditions for optimal control problems with frequency constraints on the control action trajectories. This article is a continuation of our studies to more applied problems for an important class of mechanical systems.

The configuration variables of a large class of mechanical systems (e.g., spacecraft, mobile robots, autonomous underwater vehicles [7],) evolve on matrix Lie groups. Developing a control paradigm for such a class of systems, where hard constraints on the actuators and the states, as well as frequency constraints on the control actions, would prove invaluable to the community of control practitioners. The problem described above can be stated as a constrained optimal control problem, and optimal control theoretic [5] tools such as the Pontryagin maximum principle (PMP) and dynamic programming can, in principle, be applied to them.

Optimal control problems for controlled mechanical systems evolving on non-flat manifolds cannot be solved using the discrete-time PMP on Euclidean spaces [5] because this technique does not carry over directly to such manifolds. We developed a geometric version of the PMP for constrained optimal control problems on matrix Lie groups in [8], but frequency constraints on the control actions were not considered there. A comprehensive framework for constrained discrete-time optimal control problems on matrix Lie groups with state-action constraints and frequency constraints on the control actions is needed, and in this article we establish a discrete-time geometric version of the PMP tailored to such problems. The main contribution of this article is that the technique presented here provides tractable solutions to optimal control problems, incorporating, at once, an entire class of hard constraints on the states, control actions, and frequency constraints on the control trajectories, right at the synthesis stage. The constrained two point boundary value problems arising out of the necessary conditions for optimality can be solved via multiple shooting techniques that can be implemented on a parallel architecture for fast computation.

After introducing the necessary notations, we expose the precise problem statement in §II, and follow up with the main result — a geometric discrete-time PMP on matrix Lie groups — in §III. A proof of the main result is given in §IV, and numerical experiments on spacecraft attitude control are presented in §V.
II. Problem setup

Fix a positive integer \( N \) that will play the rôle of a time horizon. For \( \mathcal{N} \in \mathbb{N}^\ast \), we set \( [N] := \{0, \ldots, N-1\} \) and \( [N]^\ast := [N] \setminus \{0\} \). Let \( G \) be a matrix Lie group with \( g \) its Lie algebra; the map \( g : G \rightarrow G \) denotes the corresponding exponential map. Recall \( 9, \) p. 273) that for each \( X \in g \), there exist a map \( \exp^X : \mathbb{R} \rightarrow G \) such that \( \exp^X(0) = e \in G \), \( \exp^X(t + s) = \exp^X(t) \exp^X(s) \), where \( e \) is the group identity. For \( y \in \mathcal{C}^N \) we let \( \text{supp}(y) := \{i \in [N]^\ast \mid y_i \neq 0\} \).

Consider a controlled discrete-time system evolving partly on a fixed matrix Lie group \( G \) and partly on \( \mathbb{R}^d \), given by

\[
\begin{align*}
q_{t+1} &= q_t s(t, q_t) \\
x_{t+1} &= f(t, q_t, u_t)
\end{align*}
\]

for \( t \in [N]^\ast \), \( (q_t, x_t) \in G \times \mathbb{R}^d \) is the vector of states and \( u_t \in \mathbb{R}^m \) the vector of control actions of the system at a discrete-time instant \( t \). The maps \( s_t : G \times \mathbb{R}^d \rightarrow G \) describing the dynamics of the states \( q_t \) on the matrix Lie group \( G \), and \( f_t : G \times \mathbb{R}^d \times \mathbb{R}^m \rightarrow \mathbb{R}^d \) describing the dynamics of state \( x_t \) in \( \mathbb{R}^d \) are smooth. We further assume that there exists an open set \( \mathcal{O} \subset g \) such that the following conditions hold:

(a) the exponential map \( g : G \rightarrow \exp(G) \) is a diffeomorphism, and

(b) the image of \( s_t \) is a subset of \( \exp(G) \) for all \( t \).

An open set \( \mathcal{O} \) satisfying the condition (a) always exists by definition of the exponential map; the condition (b) is, however, an assumption, in effect stipulating that the time-discretization step is sufficiently small.

Frequency constraints: We provide a brief discussion on discrete-time control frequency constraints. Let \( \mathbb{R}^N \ni u^{(k)} := (u_t^{(k)})_{t=0}^{N-1} \) be the trajectory of the \( k \)th component of the control. Throughout the article, the subscript on \( u \) denotes the stage and the superscript denotes the component of the control. The hat on top of a variable denotes its frequency representation. The discrete Fourier transform (DFT) of \( u^{(k)} \) is defined by \( 10 \), Chapter 7

\[
\mathcal{C}^N \ni \tilde{u}^{(k)} := F^{(k)}u^{(k)} \quad \text{for } k = 1, \ldots, m,
\]

where \( F := \frac{1}{\sqrt{N}} \begin{pmatrix} 1 & \cdots & 1 \\ 1 & \omega & \cdots & \omega^{N-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \omega^{N-1} & \cdots & \omega^{(N-1)(N-1)} \end{pmatrix} \in \mathbb{C}^{N \times N} \)

for \( \omega := e^{\frac{2\pi i}{N}} \). We let \( u \) denote the stacked vector \( (u^{(1)})^\top \ldots (u^{(m)})^\top \), and define the DFT of a control trajectory by the vector

\[
\mathbb{C}^{mN} \ni \tilde{u} := \begin{pmatrix} \tilde{u}^{(1)} \\ \vdots \\ \tilde{u}^{(m)} \end{pmatrix} = \begin{pmatrix} F^{(1)}u^{(1)} \\ \vdots \\ F^{(m)}u^{(m)} \end{pmatrix} = \mathcal{F} \begin{pmatrix} u^{(1)} \\ \vdots \\ u^{(m)} \end{pmatrix},
\]

where \( \mathcal{F} \) is a block diagonal matrix with the standard DFT matrix \( F \) being each block. Note that \( (\tilde{u}^{(k)})_j \in \mathbb{C} \) represents the \( 2\pi j/N \)th frequency component of the trajectory \( u^{(k)} \). Therefore, if elimination of the \( 2\pi j/N \)th frequency component of \( u^{(k)} \) is desired, it is ensured by introducing the constraint

\[
0 = (\tilde{u}^{(k)})_j = F_j u^{(k)},
\]

where \( F_j \) is the \( j \)th row of the DFT matrix defined above.

Therefore, in general, control frequency constraints are enforced by a collection of affine equality conditions in the control action variables, and we represent them in an abstract fashion by one equality constraint

\[
\sum_{t=0}^{N-1} \bar{F}_ju_t = 0 \quad \text{where } \bar{F}_j \text{ are suitable matrices. (2)}
\]

The reader will notice that the manner in which frequency constraints are assimilated into the problem formulation enables the designer to cancel particular frequencies in the control inputs, a feature distinctly absent in other control synthesis schemes. (A more detailed discussion on control frequency constraints may be found in [6].)

Collecting the definitions above, we write our constrained optimal control problem in discrete-time:

\[
\begin{align*}
\text{minimize} & \sum_{t=0}^{N-1} c_t(q_t, x_t, u_t) + c_N(q_N, x_N) \\
\text{subject to} & \mathcal{F} \begin{pmatrix} u_t \end{pmatrix} \in \mathcal{C}^N \quad \text{for each } t \in [N], \\
& \mathbb{C}^{mN} \ni \tilde{u} := \begin{pmatrix} \tilde{u}^{(1)} \\ \vdots \\ \tilde{u}^{(m)} \end{pmatrix} = \mathcal{F} \begin{pmatrix} u^{(1)} \\ \vdots \\ u^{(m)} \end{pmatrix},
\end{align*}
\]

with the following data:

(3-i) \( (\tilde{q}, \tilde{x}) \in G \times \mathbb{R}^d \) and \( N \in \mathbb{N} \) are fixed;

(3-ii) the maps \( c_t : G \times \mathbb{R}^d \times \mathbb{R}^m \rightarrow \mathbb{R} \), for each \( t \in [N] \) defining cost-per-stage and \( c_N : G \times \mathbb{R}^d \rightarrow \mathbb{R} \) accounting for the final stage cost are smooth;

(3-iii) the maps \( \varphi_t : G \times \mathbb{R}^d \rightarrow \mathbb{R}^m \) for \( t \in [N + 1]^* \) denote constraints on the states and are smooth;

(3-iv) the set of admissible control actions \( \mathcal{U}_t \subset \mathbb{R}^m \) is convex and compact for each \( t \in [N] \);

(3-v) the linear map \( \mathbb{R}^{mN} \ni (u_0, \ldots, u_{N-1}) \mapsto F(u_0, \ldots, u_{N-1}) := \sum_{t=0}^{N-1} \bar{F}_ju_t \in \mathbb{R}^l \) represents constraints on the frequency components of the control profile \( (u_t)_{t=0}^{N-1} \).

Remark II.1. The map \( F \) defined in (3-v) provides the real and imaginary components of the required frequency components of the control profile. In this article the main result is specialized to eliminating certain frequency components and hence we simply set the constraint \( F(u_0, \ldots, u_{N-1}) = 0 \) in (3). However, this approach can be extended to a larger class of constraints on the frequency components; see Remark IV.1 for modifications to the approach in such cases.

To state our main result, we need a few definitions from the theory of Lie groups that are relevant to this article; a detailed discussion may be found in [9, p. 124, 173, 311].

Let \( G \ni q \mapsto h(q) \in \mathbb{R} \) be a function defined on a manifold \( G \). The tangent lift of the function \( h \) at a point...
\[ q_0 \in G \] is the map
\[ T_{q_0}G + v \mapsto D_q h(q_0)v := \frac{d}{dt}h(q_0)\gamma(t) \in \mathbb{R}, \]
where \( \gamma(t) \) is a path in the manifold \( G \) with \( \gamma(0) = q_0 \) and \( \frac{d}{dt}h(q_0)\gamma(t) = v. \) Let \( \Phi : G \times G \to G \) be a left action and let \( \Phi_q : G \to G \) denote \( \Phi(g, \cdot). \) The tangent lift of \( \Phi, T\Phi : G \times G \to TG \) is the action
\[ (g, (h, v)) \mapsto T\Phi_g(h, v) = (\Phi_g(h), T_h\Phi_g(v)), \quad (h, v) \in T_hG. \]
The cotangent lift of \( \Phi, T^*\Phi : G \times G \to TG \) is the action
\[ (g, (a, v)) \mapsto T^*\Phi_g^{-1}(h, a) = (\Phi_g(h), T_{g^{-1}}(\Phi_g^{-1}(a)), a \in T^*_hG. \]
The adjoint action of \( G \) on \( g \) is defined as
\[ G \times g \ni (g, \beta) \mapsto Ad_g \beta := \left. \frac{d}{dt} \right|_{t=0} g e^{\beta t} g^{-1} \in g, \]
and finally, the co-adjoint action of \( G \) on \( g^* \) is the inverse dual of the adjoint action, given by
\[ G \times g^* \ni (g, \alpha) \mapsto Ad^*_{g^{-1}} \alpha \in g^*, \]
with \( \{Ad^*_{g^{-1}} \alpha, \beta\} = \{\alpha, Ad_g \beta\}. \]

### III. Main result

The following theorem is our main result:

**Theorem III.1.** Let \( \{w_t\}_{t=0}^{N-1} \) be an optimal control trajectory for (3) and \( \{q_t^a, x_t^a\}_{t=0}^{N-1} \) be the corresponding state trajectory. Define the Hamiltonian
\[ g \times \mathbb{R}^l \times [N] \times G \times \mathbb{R}^d \times \mathbb{R}^m \ni (q, \zeta, \tau, v, \xi, \mu) \mapsto \left( H^\zeta, \Phi(q, \zeta, \tau, v, \xi, \mu) := \nu_c_r(x_t, \mu) + \left( g, \exp^{-1}(s_t, v, \xi) \right) \right) g + \left( \zeta, f_r(x_t, \mu) + \left( \Phi(q, \tau, v, \xi, \mu) \right) \right) \in \mathbb{R}. \]

Then there exist
- adjoint trajectories \( \{\eta_t^b\}_{t=0}^{N-1} \subset \mathbb{R}^d \), \( \{\eta_t^a\}_{t=0}^{N-1} \subset g, \)
- covectors \( \eta^b_t \in \mathbb{R}^n, \) \( \eta^a_t \in \mathbb{R}^m, \)
- and a pair \( \{\eta^b, \eta^a\} \in [-1, 0] \times \mathbb{R}^\ell \)

such that, with \( \gamma_t^0 := (\eta^b_t, \eta^a_t, q_t^0, x_t^0, u_t^0) \) and \( \beta_t^b := (D \exp^{-1}(q_t^0, q_t^0), \tau, v, \xi, \mu) \in \mathbb{R} \), the following conditions hold:

1. the non-triviality condition:
   - the adjoint variables \( \{\eta_t^b\}_{t=0}^{N-1} \), \( \{\eta_t^a\}_{t=0}^{N-1} \), and the pair \( \{\eta^b, \eta^a\} \) do not simultaneously vanish;
2. the state and adjoint dynamics:
   \[ \begin{align*}
   q_{t+1}^a &= q_t^a \exp(D_q H^a)^{-\cdot} \gamma_t^0, \\
   x_{t+1}^a &= D^a H^a^{-\cdot} \gamma_t^0,
   \end{align*} \]
   \[ \begin{align*}
   \beta_{t+1}^b &= T^*\Phi_{q_t^0} \left( D_q H^b^{-\cdot} \gamma_t^0 + \eta_t^a D_q \varphi_t(q_t^a, x_t^a) \right), \\
   \eta_{t+1}^b &= D^b H^b \gamma_t^0, \quad \eta_{t+1}^a = D^a E \varphi_t(x_t^a).
   \end{align*} \]
3. the transversality conditions:
   \[ \begin{align*}
   \beta_{N-1}^b &= T^*\Phi_{q_N^0} \left( D_q c_N(q_N^a, x_N^a) + \eta_N^a D_q \varphi_N(q_N^a, x_N^a) \right), \\
   \eta_{N-1}^b &= \eta^E c_N(q_N^a, x_N^a).
   \end{align*} \]

1. The left action on a Lie group should not be confused with control actions in the context of our control system.

**Remark III.1.** The adjoint variables (a.k.a. ‘multipliers’,) corresponding to the cost, the dynamics, the state-constraints, and the frequency constraints of the control trajectories appear here, and we distinguish between them by introducing the different super-scripts of the single Greek letter \( \eta \). Various objects in frequency space are distinguished by a ‘hat’. In particular, the two adjoint variables that are constant with time appear in the superscript of the Hamiltonian.

### IV. Proof of the main result

In this section we first provide a sketch of a proof of Theorem III.1, and subsequently elaborate on each step of the proof.

(S-i) The frequency constraints are represented as an auxiliary dynamical system that is incorporated into the optimal control problem.

(S-ii) We define a diffeomorphism to translate the optimal control problem obtained in step (S-i) to an equivalent optimal control problem on a Euclidean space of appropriate dimension.

(S-iii) The optimal control problem obtained in (S-ii) is converted to a static optimization problem, and first order necessary conditions for optimality are derived using Boltyanskii’s method of tents [5].

(S-iv) The first order necessary conditions are mapped from the form of the linear controlled dynamical system in an auxiliary variable \( w \) as follows:

\[ w_{t+1} = w_t + F_t u_t, \quad w_0 = 0 \in \mathbb{R}^\ell. \]

To wit, the frequency constraints in (3) are defined via the linear maps \( F_t : \mathbb{R}^m \to \mathbb{R}^\ell \) defined in (2). We recast these constraints in the form of a linear controlled dynamical system in an auxiliary variable \( w \) as follows:

\[ w_{t+1} = w_t + F_t u_t, \quad w_0 = 0 \in \mathbb{R}^\ell. \]

We write (3) in a standard form:

\[ \text{minimize} \sum_{t=0}^{N-1} c_t(q_t, x_t, u_t) + c_N(q_N, x_N) \]

subject to

\( \text{dynamics (1) and (5),} \quad u_t \in U_t \quad \text{for each} \ t \in [N], \)

\( \varphi_t(q_t, x_t) \leq 0 \quad \text{for each} \ t \in [N + 1]. \)

\( (q_0, x_0, w_0) = (\tilde{q}, \tilde{x}, 0), \) and \( w_N = 0. \)
Remark IV.1. With the auxiliary system defined as in (5), the final states $w_N$ correspond to the real and imaginary parts of the required/chosen frequency components. Therefore constraints on the frequency components of the control profile translate to final state constraints on the auxiliary states.

$(S\text{-ii}):$ Translation of (6) to Euclidean space: Let us define a parametrization of the Lie group $G$ in an open neighborhood of $q_t$ for each $t \in [N+1]$. Define an open neighborhood of $q_t$ as $Q_t := \{q | g \in \exp(O)\}$, where $O$ is an open set in the Lie algebra $\mathfrak{g}$ containing 0. Then for a given $q_t \in G$, the map $\phi_q := \{\Phi_q \circ \exp\}^{-1} : Q_t \rightarrow \sigma$ lends a unique representative for $q_{t+1} \in G$ on the Lie algebra $\mathfrak{g}$ for all $t \in [N]$.

Since $G$ is a matrix Lie group, the corresponding Lie algebra $\mathfrak{g}$ is a finite dimensional vector space, and hence there exists a linear homeomorphism $\sigma : \mathfrak{g} \rightarrow \mathbb{R}^{n_q}$, where $n_q$ is the dimension of Lie algebra $\mathfrak{g}$. The linear homeomorphism $\sigma$ further translates the dynamics from the Lie algebra to an Euclidean space. We now provide a detailed description of the translation of the optimal control problem to the Euclidean space. For the sake of brevity, define $q := (q_0, \ldots, q_N), \ x := (x_0, \ldots, x_N), \ u := (u_0, \ldots, u_N)$, and a product manifold

$$M := G^{N+1} \times \mathbb{R}^{d(N+1)} \times \mathbb{R}^{(N+1) \times \mathbb{R}^{mN}},$$

such that every state and action trajectory corresponds to a unique point on $M$, i.e., $(q, x, w, u) \in M$.

We define a map from the open set

$$\Lambda \ni (\beta, x, w, u) \mapsto \Psi(\beta, x, w, u) := (\psi_0(\beta), \ldots, \psi_N(\beta), x, w, u) \in \Psi(\Lambda),$$

where for $t \in [N+1]$ and a fixed $\bar{q} \in G$,

$$\psi_t(\beta) := \bar{q} \exp(\sigma^{-1}(\beta_0)) \cdots \exp(\sigma^{-1}(\beta_t)).$$

Observe that the map $\Psi$ is a smooth bijection whose inverse is given by the smooth map

$$\Psi^{-1}(\alpha, x, w, u) \mapsto \Psi^{-1}(\alpha, x, w, u) :=\left((\sigma \circ \exp^{-1})(\bar{q}^{-1} \alpha_0), \ldots, (\sigma \circ \exp^{-1})(\alpha_{N-1}^{-1} \alpha_N), x, w, u\right).$$

In other words, $\Psi$ is a diffeomorphism. It is important to note that all the feasible state-action trajectories of (6) lie in the image of $\Psi$ as discussed in [8]. We employ the diffeomorphism $\Psi$ to translate (6) from the manifold $M$ to the Euclidean space, and for $p := (p_0, \ldots, p_N) \in \mathbb{R}^{(N+1)n_q}$, we arrive at

$$\begin{aligned}
\minimize_{(w_t)_{t=0}^{N-1}} \sum_{t=0}^{N-1} c_t(\psi_t(p), x_t, u_t) + c_N(\psi_N(p), x_N) \\
\text{subject to} \quad \begin{cases}
p_{t+1} = (\sigma \circ \exp^{-1} \circ s_t)(\psi_t(p), x_t) \\
x_{t+1} = f_t(\psi_t(p), x_t, u_t) \\
w_{t+1} = w_t + \bar{F}_t u_t \\
\psi_t(p), x_t, u_t \in \Omega_t \\
p_{00} = (0, \bar{x}, 0), \quad w_N = 0.
\end{cases}
\end{aligned}$$

$(S\text{-iii}):$ From optimal control to optimization: Although the optimal control problem (8) is defined on a Euclidean space, the standard discrete-time PMP cannot be applied directly since the map $\psi_t$ appearing on the RHS of the first two equations leads to memory in the dynamics, i.e., $\psi_t$ depends on not just the current values of the states and control, but on the previous values as well. To circumvent this, we lift the optimal control problem to a static optimization problem in a higher-dimensional Euclidean space and apply Boltyanskii’s method of tents [5] to this lifted optimization problem.

To this end, let $z := (p, x, w, u) \in \mathbb{R}^n$, where $n := (n_q + d + f(N + 1) + mN)$ is the stacked vector of states and control corresponding to (8). We define projection maps that allow us to access each component of $z$ as follows:

$$\begin{aligned}
p_t^p(z) &:= p_t, \quad \pi_t^x(z) := x_t, \quad \pi_t^w(z) := w_t \quad \text{for} \quad t \in [N + 1], \\
p_0^w(z) &:= u_t \quad \text{for} \quad t \in [N] \quad \text{and} \quad \pi^p(z) := p.
\end{aligned}$$

(9)

We lift the cost function and the constraints of (8) to $\mathbb{R}^n$ using the projection maps (9) as follows:

- The condition $u_t \in \mathbb{U}_t$ becomes $\Omega_t^0 := \{z \in \mathbb{R}^n \mid \pi_t^w(z) \in \mathbb{U}_t\}$.
- The end-point constraints on the states are described by $\Omega_0 := \{z \in \mathbb{R}^n \mid \pi_0^w(z) = 0, \pi_0^x(z) = \bar{x}, \pi_0^u(z) = 0\}$ and $\Omega_N := \{z \in \mathbb{R}^n \mid \pi_N^x(z) = 0\}$.
- The cost functions, the dynamics and the state constraints are described by:

$$\begin{aligned}
C(z) &:= \sum_{t=0}^{N-1} c_t(\psi_t(\pi(t)), \pi_t^x(z), \pi_t^w(z)) + c_N(\psi_N(\pi(p)), \pi_N^x(z)) \\
F_0^p(z) &:= -\pi_0^p(z) + (\sigma \circ \exp^{-1}) \circ s_0(\psi_0(\pi(p)), \pi_0^x(z)) \\
F_t^x(z) &:= -\pi_t^x(z) + f_t(\psi_t(\pi(p)), \pi_t^x(z), \pi_t^w(z)) \\
F_t^w(z) &:= -\pi_t^w(z) + \bar{F}_t \pi_t^w(z) \\
G_t(z) &:= \phi_t(\psi_t(\pi(p)), \pi_t^x(z))
\end{aligned}$$

We now arrive at a static optimization problem equivalent to the optimal control problem (6):

$$\begin{aligned}
\minimize_z \quad C(z) \\
\text{subject to} \quad \begin{cases}
F_0^p(z) = 0 \\
F_t^x(z) = 0 \quad \text{for} \quad t \in [N] \\
F_t^w(z) = 0 \\
G_{t+1}(z) \leq 0 \\
z \in \left(\bigcap_{t=0}^{N-1} \Omega_t^0\right) \cap \Omega_0 \cap \Omega_N.
\end{cases}
\end{aligned}$$

(10)
Suppose that \((q^o, \theta^o, \omega^o, u^o)\) is an optimal state-action trajectory for the optimal control problem (6). Then \(z^o : = \Psi^{-1}(q^o, \theta^o, \omega^o, u^o)\) is a solution of above optimization problem. By [5, Theorem 18], there exist multipliers (row vectors) \(\eta_t^r, (\eta_t^r)_{t=0}^{N-1}, (\eta_t^r)_{t=0}^{T}, \eta_t^r)_{t=1}^N \in \mathbb{R} \times \mathbb{R}^{n_1(N+1)} \times \mathbb{R}^{d(N+1)} \times \mathbb{R}^{f(N+1)} \times \mathbb{R}^{ru(N+1)}, \) not all simultaneously zero, such that

\[
\begin{aligned}
\eta_t^r D_z C(z^o) + \sum_{t=0}^{N-1} \eta_t^r D_z F_t^r(z^o) + \sum_{t=0}^{N-1} \eta_t^r F_t^r(z^o), \zeta \\
+ \sum_{t=0}^{N-1} \eta_t^r D_z F_t^r(z^o) + \sum_{t=0}^{N-1} \eta_t^r D_z G_t(z^o, \zeta) & \leq 0 \\
\end{aligned}
\]

for \(z^o + \zeta \in \bigcap_{t=0}^{N-1} Q^r_t(z^o) \cap Q^r_t(z^o) \cap Q^+_{u^o}(z^o), \)

where \(Q^r_k(r)\) represents a tent of the set \(K \in \mathbb{R}^k\) as defined in [5, §3], and for each \(j \in \{n_1 + 1\}, (\eta_t^r)^r_j \leq 0\) and \((\eta_t^r)^r_j G_t^r(z^o) = 0\) for each \(t \in [N+1]^r\).

(S-iv) First order necessary conditions in the configuration space: We push back the optimality condition (11) to the configuration manifold \(M\). Let \(\tilde{z}^o = \sigma^r(\eta_t^r)\).

Adjoint of the states \(x\): For each \(t \in [N]^r\), if we choose \(\tilde{z}^o\) in (11) such that all its entries except those in \(\eta_t^r(\tilde{z}^o)\) are zero, then,

\[
\begin{aligned}
\langle \eta_t^r D_x c_t(q_t^o, x_t^o, u_t^o), x_t^o, u_t^o \rangle + \langle \eta_t^r D_x \psi_t(q_t^o, x_t^o, u_t^o), \eta_t^r(\tilde{z}^o) \rangle \\
+ \langle \eta_t^r D_x (\exp(-s_0) q_t^o, x_t^o, u_t^o), \pi_t^o(\tilde{z}^o) \rangle \\
+ \langle \eta_t^r D_x f_t(q_t^o, x_t^o, u_t^o) \rangle & \leq 0 \\
\end{aligned}
\]

where \(\pi_t^o(\tilde{z}^o) \in \mathbb{R}^d\) can be arbitrary, in view of the Hamiltonian defined in (4), the inequality (12) reduces to the dynamics of the adjoints \(\eta_t^r\) in (ii). An identical procedure can be adopted to derive the transversality condition for \(\eta_t^r(\tilde{z}^o)\), in (iii) after setting all entries of \(\tilde{z}^o\) in (11) to zero except \(\eta_t^r(\tilde{z}^o)\).

Adjoint of the (auxiliary) states \(w\): For each \(t \in [N]^r\), we choose \(\tilde{z}^o\) in (11) such that all its entries except those in \(\eta_t^r(\tilde{z}^o)\) are zero. The optimality condition (11) then leads to \(\eta_t^r(\tilde{z}^o) = 0\), \(\eta_t^r(\tilde{z}^o) \leq 0\). Since \(\eta_t^r(\tilde{z}^o) \in \mathbb{R}^\ell\) can be picked arbitrarily, \(\eta_t^r = \eta_t^0 = \cdots = \eta_t^N = 0\) this is our ‘multiplier’ corresponding to the frequency constraints.

Adjoint of the configurations \(q\): Let \(\tilde{q}_t := D_p \psi_t(\pi^r(\tilde{z}^o))\pi^r(\tilde{z}^o) \in T_{q_t^o} G\) for \(t \in [N+1]\), (cf. (11)) be the velocity vector at the configuration \(q_t^o\) and \(\chi_t := T_{q_t^o} \Phi_{q_t^o}(\tilde{q}_t) \in q_t^o\) be its corresponding vector in the Lie algebra \(q\). Therefore

\[
T_{q_t^o} \Phi_{q_t^o}(\chi_t) = D_p \psi_t(\pi^r(\tilde{z}^o)) \pi^r(\tilde{z}^o) \in T_{q_t^o} G, t \in [N+1],
\]

and \(\pi^r(\tilde{z}^o)\) can be obtained via the tangent lift of \(\Psi^{-1}\) with \(k_{t-1} := \mathcal{D} \exp^r((q_{t-1}^o)^{-1} q_t^o) \circ T_{\Phi(q_{t-1}^o)^{-1}} q_t^o\) as \(\pi_t^r(\tilde{z}^o) := \sigma(\chi_t)\) and

\[
\pi_t^r(\tilde{z}^o) = -\sigma \circ k_{t-1}(Ad q_{t-1}^o (\chi_t - \chi_{t-1})) \text{ for } t \in [N+1]^r.
\]

If we choose \(\tilde{z}^o\) in (11) such that all its entries except \(\pi^r_t(\tilde{z}^o)\) are zero, then by substituting \(\pi^r_t(\tilde{z}^o)\) from (14) and using (13), (11) reduces to

\[
\begin{aligned}
& \sum_{t=0}^{N-1} \langle \eta_t^r D_n c_t(q_t^o, x_t^o, u_t^o), x_t^o, u_t^o \rangle + \langle \eta_t^r D_n \psi_t(q_t^o, x_t^o, u_t^o), \eta_t^r(\tilde{z}^o) \rangle \\
& + \langle \eta_t^r D_n (\exp(-s_0) q_t^o, x_t^o, u_t^o), \pi_t^o(\tilde{z}^o) \rangle \\
& + \langle \eta_t^r D_n f_t(q_t^o, x_t^o, u_t^o) \rangle & \leq 0 \\
\end{aligned}
\]

Since \(\chi_t \in q_t^o\) can be selected arbitrarily for all \(t \in [N+1]^r\), we choose a sequence \((\chi_t)_{t=0}^N\) such that \(\chi_t = 0\) for all \(t \in [N+1]^r, t \neq r\). In view of the above and by definition of the Hamiltonian (4), (15) reduces to the dynamics of \(\eta^o_t\) in (ii) and the transversality condition of \(\eta^o_N(\tilde{z}^o)\) in (iii) of Theorem III.1.

Conditions on the control: Note that \(U_t \in \mathbb{R}^d\) is convex, and therefore, \(U_t \subset Q_{U_t}(u_t^o)\). We restrict \(\tilde{z}^o\) such that \(\tilde{u}_t + u_t^0 \in Q_{U_t}(u_t^o)\), which simplifies the condition (11) to

\[
\begin{aligned}
\langle \eta_t^r D_n c_t(q_t^o, x_t^o, u_t^o), x_t^o, u_t^o \rangle + \langle \eta_t^r D_n \psi_t(q_t^o, x_t^o, u_t^o), \omega - u_t^o \rangle \\
+ \langle \eta_t^r D_n f_t(q_t^o, x_t^o, u_t^o) \rangle & \leq 0 \text{ for all } \omega \in U_t.
\end{aligned}
\]

By definition of the Hamiltonian (4), the preceding condition is equivalent to (iv) of Theorem III.1.

V. Numerical experiments

We illustrate our theory in the context of a spacecraft attitude manoeuvre, where the configuration manifold is the matrix Lie group \(SO(3)\) (the set of \(3 \times 3\) real orthogonal matrices with determinant 1) and its Lie algebra is \(so(3)\) (the set of \(3 \times 3\) real skew-symmetric matrices).

Satellite attitude dynamics: Let \(R_t\) and \(P_t\) in \(SO(3)\) be the rotation matrices that relate coordinates of a point in the spacecraft body frame to the inertial frame and the change in the orientation at \(t^r\)th time instant respectively. Let \(\Pi_t \in \mathbb{R}^3\) be the spacecraft momentum vector in the body frame, and \(u_t \in \mathbb{R}^3\) be the torque applied to the spacecraft in the body frame. Assuming that a constant control is applied between two discrete-time instants for a step length \(h > 0\) (selected so that the conditions (a) and (b) in §II are met), the discrete-time attitude dynamics in this setting is given in the spacecraft body frame in a standard way as

\[
\begin{aligned}
R_{t+1} = & R_t P_t, \\
\Pi_{t+1} = & P_t^T \Pi_t + h u_t, \\
h \Pi_t = & P_t J_t \bar{J}_t d_t, \bar{J}_t d_t.
\end{aligned}
\]

where \(J_t = tr(J_t) - \mathcal{J} \) and \(\mathcal{J} \) is the moment of inertia matrix. A detailed derivation of the system dynamics is given in, e.g. [11]. The data for our numerical experiments are:
| System Parameters and Specifications | Admissible range |
|-------------------------------------|------------------|
| the principal moment of inertia of  | (800, 1200, 1000) kg m² |
| the spacecraft \( \{ J_x, J_y, J_z \} \) | 0.1 s |
| the sampling time \( (T) \) | [10 °, 90 °] |
| the maximum admissible torque | (20, 20, 20) N m |
| bound (control bound) \((u_{bd})\) | 0 above 2π/3 |
| the maximum momentum \((\Pi_{bd})\) | no restriction |
| range of the time duration \((t_{max})\) of | 5 s and 30 s |
| manoeuvres | |

**Problem definition:** The control objective is to synthesize an energy-optimal control profile to manoeuvre a spacecraft from the initial state \((R_i, \Pi_i)\) to the final state \((R_f, \Pi_f)\) in \(N\) discrete-time instances while satisfying the following state and control constraints:

\[
\begin{align*}
    \left| u^{(i)}_{t_i} \right| & \leq u^{(i)}_{bd} \\
    \left| \Pi^{(i)}_{t_i} \right| & \leq \Pi^{(i)}_{bd} \\
    \text{supp}(u^{(i)}_{t_i}) & \subset \mathcal{W}_i
\end{align*}
\]

where \( \mathcal{W}_i := \{ i \mid \frac{2\pi(i-1)}{N} \leq \frac{2\pi}{3} \text{ or } \frac{2\pi(i-1)}{N} \geq \frac{4\pi}{3} \} \) for \( i = 1, 3 \)

and \( \mathcal{W}_2 = \{ 1, \ldots, N \} \) denote the set of allowable frequencies in the torque profile \( u^{(i)} \), \( u^{(b)} \in \mathbb{R}^+ \) denotes the torque bound on the actuator along \( i \)-th axis and \( \Pi^{(i)}_{bd} \in \mathbb{R}^+ \) denotes the momentum bound along \( i \)-th axis.

Our frequency-constrained optimal control problem is:

\[
\begin{align*}
    \text{minimize} & \quad J(u) := \sum_{t=0}^{N-1} \frac{1}{2} ||u_t||^2 \\
    \text{subject to} & \quad \text{dynamics (16) and constraints (17).}
\end{align*}
\]

**Trajectory generation:** We present a manoeuvre for reorienting the spacecraft by \( 50^\circ \) about the axis \( (\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}, 0) \) in the body frame from an initial momentum \( \Pi_i = (0, 0, 0) \) N m s to a desired final momentum \( \Pi_f = (0, 0, 0) \) N m s in 13s. The frequency components of the torque profiles along the \( x \)- and \( z \)-axes actuators that are above \( 2\pi/3 \) are set to be zero by an appropriate choice of matrices \( \mathcal{F}_i \), and the one along the \( y \)-axis is left unconstrained; Figure 2 reflects the outcome. The optimal controls and the corresponding momentum profiles are shown in Figure 1 and Figure 3 respectively. Observe that the optimal control along the \( x \)- and \( y \)-axes saturates for the time duration \( 1-2s \) in order to execute the pre-specified manoeuvre within the given time interval, and that the optimal control along the \( y \)-axis becomes zero for the time duration \( 6.2-7s \) since the momentum constraints along \( y \)-axis are active for that duration.

**Fig. 1:** Optimal control profiles.

**Fig. 2:** Frequency spectra of the optimal controls.

**Fig. 3:** Optimal momentum profiles.
