Abstract
Our goal is to provide a novel method of representing 2D shapes, where each shape will be assigned a unique fingerprint—a computable approximation to the conformal map of the given shape to a canonical shape in 2D or 3D space (see page 22 for a few examples). In this paper, we make the first significant step in this program where we address the case of simply and doubly connected planar domains. We prove uniform convergence of our approximation scheme to the appropriate conformal mapping. To this end, we affirm a conjecture raised by Ken Stephenson in the 1990s which predicts that the Riemann mapping can be approximated by a sequence of electrical networks. In fact, we first treat a more general case. Consider a planar annulus, i.e., a bounded, 2-connected, Jordan domain, endowed with a sequence of triangulations exhausting it. We construct a corresponding sequence of maps which converge uniformly on compact subsets of the domain, to a conformal homeomorphism onto the interior of a Euclidean annulus bounded by two concentric circles. The resolution of Stephenson’s conjecture then follows by a limiting argument. With more complex topology of the given shape, i.e., when it has higher genus, we will use methods invented by Arabnia (J Parallel Distrib Comput 10:188–192, 1990) and Wani–Arabnia (J Supercomput 25:43–62, 2003). First, to divide the domain into subdomains and thereafter to make the scheme presented in this paper suitable for parallel processing. We will then be able to compare our results for those appearing, for instance, in the work of Arabnia–Oliver (Comput Graph Forum 8:3–11, 1989) that provides algorithms for the translation and scaling of complicated digitalized images.

1 Introduction

1.1 Riemann’s mapping theorem and Thurston’s disk packing scheme

The Riemann mapping theorem asserts that any simply connected planar domain, which is not the whole plane, can be mapped bi-holomorphically onto the open unit disk. That is, the domains are conformally equivalent. After a suitable normalization, this mapping is called the Riemann mapping and it is desirable to have a concrete approximation of it. In [48], Rodin and Sullivan proved Thurston’s celebrated conjecture [58] asserting that a scheme based on the Koebe–Andreev–Thurston disk packing theorem (cf. [1,2,41,59]) converges to the Riemann mapping.

In order to formulate Thurston’s conjecture, which inspired Stephenson’s conjecture, we need to recall a few definitions. Let \( P \) be a disk packing in the complex plane \( \mathbb{C} \). An interstice is a connected component of the complement of \( P \), and one whose closure intersects only three disks in \( P \) is called a triangular interstice. We will let \( \text{supp}(P) \) denote the union of the disks in \( P \) and all its bounded interstices, and we will assume that it is simply connected. The disks of \( P \) that intersect the boundary of its support are called boundary disks. Two finite disk packings, \( P \) and \( \tilde{P} \) in \( \mathbb{C} \), will be called isomorphic, if there exists an orientation preserving homeomorphism \( \phi: \text{supp}(P) \rightarrow \text{supp}(\tilde{P}) \) such that \( \phi(P) = \tilde{P} \). It is clear that such an isomorphism induces a bijection between the disks of \( P \) and the disks of \( \tilde{P} \).

Let \( \Omega \subset \subset \mathbb{C} \) be a bounded, simply connected domain, and let \( p_0 \) be an interior point in it. For each positive integer \( n \), let \( P^n \) be a disk packing in \( \Omega \) in which all bounded interstices are triangular. Assume that there is a sequence of positive numbers \( \delta_n \) which converges to zero, such that: (i) the radius of every disk in \( P^n \) is smaller than \( \delta_n \), and (ii) every boundary disk in \( P^n \) is at most the distance of \( \delta_n \) from \( \partial \Omega \). Finally, let \( P^n_0 \) be a selected disk in \( P^n \) which is closest to \( p_0 \) or contains it.

The disk packing theorem (Koebe–Andreev–Thurston) implies that there exists an isomorphic packing \( \tilde{P}^n \) in the closed unit disk \( \bar{D} \) with all of its boundary disks tangent to the unit circle \( S^1 \). Furthermore, if the given graph is isomorphic to the 1-skeleton of a triangulation of the Riemann sphere, then the packing is unique up to applying a Möbius transformation. Let

\[
 f_n : \text{supp}(P^n) \rightarrow \text{supp}(\tilde{P}^n) \tag{1.1}
\]

be an isomorphism of \( P^n \) and \( \tilde{P}^n \). Furthermore, normalize \( \tilde{P}^n \) by a sequence of Möbius transformations preserving \( U \) so that \( \tilde{P}^n_0 \), the disk corresponding to \( P^n_0 \) is centered at the origin. Thurston conjectured that if the packings \( P^n \) are chosen to be sub-packings of scaled copies of the infinite hexagonal disk packing of \( \mathbb{C} \), then the sequence of piecewise affine maps (i.e., simplicial) \( f_n \) converges uniformly on compact subsets of \( \Omega \) to the Riemann mapping from \( \Omega \) to \( \mathbb{D} \).

Rodin and Sullivan [48] proved Thurston’s Conjecture by first showing that the maps \( f_n \) are \( K \)-quasi-conformal, for some fixed \( K \). Hence, there exists a subsequence which will converge to a limit function \( f \) which must also be \( K \)-quasi-conformal. Rodin and Sullivan further showed that \( f \) must be 1-quasi-conformal, and therefore, \( f \) is in fact conformal. He and Schramm [31, Theorem 1.1] developed profound
techniques which avoid the machinery of quasi-conformal mapping that is heavily used in Rodin–Sullivan’s proof. Up to date, their theorem and advances [32] in the simply connected case are the most advanced. See also their related work on Koebe’s Conjecture in [33].

Chow and Luo [15] discovered applications of disk packing to the study of discrete Ricci flow on surfaces; see also the work of Glickenstein [23] for related study. There are also applications of circle packings to algorithmic computer vision and computational conformal geometry due to Gu, Luo and Yau, Gu, Zeng, Zhang, Luo and Yau, and Sass, Stephenson and Brock (cf. [27,28,49,62] as examples and further advances). More recently, taking a complementary approach to the one in this paper, Gu et al. [29] have developed powerful tools establishing several important results concerning discrete uniformization of polyhedral surfaces.

1.2 Electrical networks and Stephenson’s conjecture

In his attempts to prove uniformization, Riemann suggested considering a planar annulus as made of a uniform conducting metal plate. When one applies voltage to the plate, keeping one boundary component at a fixed voltage $k$ and the other at the voltage 0, electrical current will flow through the annulus. The equipotential sets form a family of disjoint, simple closed curves foliating the annulus and separating the boundary curves. The current flow sets consist of simple disjoint arcs connecting the boundary components, and they also foliate the annulus. Together, the two families provide curved “rectangular” coordinates on the annulus that can be used to turn it into a right circular cylinder, or into a (conformally equivalent) circular concentric annulus.

An electrical circuit or network is a collection of nodes and connecting wires. For instance, a disk packing of a fixed planar domain induces such a network where each center of a disk corresponds to a node and a wire connects each pair of nodes corresponding to tangent boundaries. It is therefore reasonable to conjecture that if the domain is made of thin conducting material then its electrical behavior can be approximated by a sequence of networks that approximates its shape.

Stephenson’s conjecture from the 1990s (see page 63 and Definition 6.5.1 in [56]) is concerned with constructing such an approximation:

**Conjecture 1.1** (Stephenson [56]) Given a sequence of networks approximating a simply connected, bounded, Jordan domain arising, for instance, from a sequence of disk packing, choose conductance constants along the edges (for each network) according to Eq. (2.1). Then the sequence of discrete potentials and currents will converge to the ones induced by the Riemann mapping.

We have phrased this conjecture in the more recent formulation of (2.4) (see Sect. 2 for the details). In fact, a similar conjecture can be formulated for any domain that can be approximated (in a sense that we will make precise in Sect. 4.4) by a sequence of quasi-uniform triangulations (see Definition A.3) that exhaust the given domain.

In Theorem 4.7, we will formalize and affirm Stephenson’s conjecture in the case of an annulus by methods that are different from the ones used in his paper or those mentioned in Sect. 1.1. In particular, we will show that there exists a large class of
networks for which the conjecture holds. We will also affirm this conjecture in its original form, i.e., for simply connected domains in the complex plane.

1.3 The themes of this paper

There is a classical and elaborate theory of conformal uniformization for domains in the Riemann sphere that are bounded by Jordan curves. Let \( \Omega \) be such a domain which is also finitely connected. Koebe proved [40] that \( \Omega \) is conformally homeomorphic to some domain \( \Omega^* \) whose boundary components are circles. Such a domain is called a circle domain. Furthermore, \( \Omega^* \) is unique up to Möbius transformations.

Discrete uniformization schemes have traditionally been the first step in constructing a sequence of approximations to a conformal map from the given domain (more on this in Sect. 1.1). There is much interest and effort by, for example, Cannon, Floyd, and Parry, to provide sufficient combinatorial conditions under which, discrete schemes based on the discrete extremal length method, will converge to a conformal map in the cases of triangulated annulus or a quadrilateral; see, for instance, [10] for the starting point and [11] for their most recent work. However, Schramm showed [51, page 117] that if one attempts to use the combinatorics of the hexagonal lattice alone, square tilings (as constructed by Schramm’s method) cannot be used as discrete approximations for the Riemann mapping.

In a different vein, of much current and recent interest is the universality of the critical Ising and other lattice models where discrete complex analysis on graphs played a crucial role (see for instance [12,20]).

In this paper, stemming from our work in [30,34–36], we will prove that a certain discrete scheme yields convergence of the mappings described below to a canonical conformal mapping from a given polygonal, planar, annulus, onto the interior of a Euclidean annulus bounded by two concentric circles.

Specifically, the underlying idea of this paper is rooted in a foundational feature of two-dimensional conformal maps. If \( f: \mathbb{D} \to \mathbb{C} \) is a conformal map, then the Cauchy–Riemann equations imply that \( \Re(f) \) and \( \Im(f) \) are harmonic functions, and that \( \Im(f) \) is the harmonic conjugate of \( \Re(f) \). For instance, when \( (r, \theta) \) are polar coordinates in the plane, we have that \( u(r, \theta) = \log r \) and \( v(r, \theta) = \theta \) (when \( \theta \) is single valued) are harmonic functions, and \( v(r, \theta) \) is the harmonic conjugate of \( u(r, \theta) \). Indeed, in this paper, we will work with the pair \( (g, \tilde{g}^*) \) which are combinatorial functions defined on the triangulation and its Voronoi dual (to be explained later).

In Theorem 4.7, we will show that under certain geometric restrictions on the sequence of triangulations, where each triangulation is endowed with the conductance constants defined according to Eq. (2.1), the sequence of combinatorially defined functions

\[
\phi_n = \exp \left( \frac{2\pi}{\text{period}(\tilde{g}_n)} (g_n + i \tilde{g}_n^*) \right),
\]

will converge uniformly on compact subsets of a given annulus, to the conformal uniformizing map of the annulus whose form is well understood (see, for instance, [17, Section 7] or [60, Theorem 4.3]).
To this end, we will employ $L_\infty$ convergence results from the theory of the finite element method, techniques from discrete potential theory, and classical results from the theory of functions of one complex variable concerning compactness of sequences of holomorphic mappings, and partial differential equations. In order to put some of the needed advances over previous work in context, let us briefly recall an inspiring work by Dubejko [19]. Let $w$ denote the solution of the Dirichlet problem $\Delta w = f$ for $x \in \Omega$, and $w = \phi$ for $x \in \partial \Omega$, where $\Omega$ is a simply connected, bounded, Jordan domain with $C^2$ boundary, where $f \neq 0 \in L^2(\Omega)$ and $\phi \in C^0(\Omega)$. By applying techniques from the finite volume method, Dubejko proved that $w$ can be approximated (in various norms) by a sequence of solutions of discrete Dirichlet boundary value problems. These solutions belong to a certain Sobolev space and are constructed via a sequence of triangulations (with special properties) that gets finer while exhausting $\Omega$ from the inside. Dubejko’s work, which utilized Stephenson’s conductance constants in the setting of the finite volume method (see [21]), is not sufficient for constructing approximations of conformal maps from Jordan domains. In fact, already in the simply connected case his techniques are not sufficient. This is due to the following reasons: His methods can be applied only under the assumption that the boundary of $\Omega$ is $C^2$; second, Dubejko did not address the problem of defining a combinatorial analogue of the harmonic conjugate; finally, Dubejko applied the Riemann’s mapping theorem in his proof.

In order to overcome some of these issues, we will employ a foundational result from the theory of the finite element method [50, Theorem 4.1]. This result will provide the $L_\infty$ convergence of the (normalized) $g_n$’s, which are different from the ones used by Dubejko, to the real part of the uniformizing map of an annulus with continuous boundary. Once this convergence result is applied, one novel part of this work is introducing a combinatorial analogue of the harmonic conjugate function and proving its convergence to its analytical counterpart.

1.4 Organization of the paper

In Sect. 2, we start by recalling the definition of the conductance constants suggested by Stephenson in his conjecture (Conjecture 1.1). We then express these in the way they are going to be utilized in Theorem 4.7, the main theorem of this paper, which proves that a certain discrete scheme converges to a uniformizing map of a planar annulus.

In Sect. 3, we present three novel definitions. First, we define the class of discrete asymptotic harmonic functions. Intuitively, a function in this class is almost harmonic on a scale determined by the mesh of the triangulation. Since our discrete approximations of $\Re(f)$, the smooth uniformizing map of an annulus, is not discrete harmonic, introducing this class of functions is essential to the approximation process described in the main theorem of this paper. Second, the flux following path is contained in the one skeleton of a given triangulation; it is used to determine the amount of discrete flux of a function which “crosses” a path in the one skeleton of the Voronoi cells of the given triangulation. Finally, if $g$ is a discrete harmonic or a discrete asymptotic
harmonic function, by summing the discrete flux along such paths, we are able to define a conjugate function $\tilde{g}^*$ of $g$ and thereafter to prove its convergence.

Section 4 is devoted to the approximation of a uniformizing map of a planar annuli with a continuous Jordan boundary. We first study the case of a polygonal annulus. In Theorem 4.7, we prove the uniform convergence of our proposed discrete scheme on compact subsets of the interior of the given annulus, to a conformal homeomorphism. We are then concerned with the approximation of the uniformization of an annulus with continuous Jordan boundary. Corollary 4.10 demonstrates that Theorem 4.7 coupled with a generalization of a compactness theorem due to Koebe and a diagonalization process allows the weakening of the boundary regularity assumption of Theorem 4.7 from polygonal to continuous.

Section 5 is devoted to the proof of Theorem 5.1, where we provide an approximation of the uniformization of a bounded, simply connected Jordan domain, the setting in which Stephenson’s conjecture (Conjecture 1.1) was first stated. The idea is to present the punctured domain as an increasing sequence of annuli. Thus, one can apply Theorem 4.7 to each annulus in the sequence. The existence of a converging subsequence of the maps obtained in each step to a bounded, conformal, univalent map is then proved (following the same rationale as in Corollary 4.10), and we can therefore restrict attention to the case that the boundary of the domain is polygonal. Finally, the Riemann’s removable singularity theorem is used to show that the sequence of the above conformal maps is bounded and hence can be extended over the puncture.

With the aim of making this paper self-contained, it contains an “Appendix.” In “Appendices A.1 and A.2”, we collect a few important notations, definitions and theorems from the finite element method that are applied in this paper. The reader, who is familiar with this method, can skip these sections. However, Theorem 4.2, which is quoted from [50, Theorem 4.1], is essential for the $L_\infty$ convergence analysis results of this paper. In “Appendix A.2”, we describe the relation between Stephenson’s conductance constants and the theory of the finite volume element method.

2 Electrical networks induced by disk packings and Stephenson’s conductances

Let us recall a few definitions and some notation from [18,19,56,57] in order to express the conductance constants suggested by Stephenson. Let $P$ be a Euclidean disk packing of a domain $\Omega$ for a complex $K$, i.e., the contact graph of $P$ is isomorphic to $K$. For an interior edge $(u, v) \in K$, consider the tangent circles, $c_v$ and $c_u$, as depicted in the figure below. Let $c_x, c_y$ be their common neighboring circles (Fig. 1).

The radical center, $w_x$, of the triple $\{c_v, c_u, c_x\}$ of circles will denote the center of the circle that is orthogonal to $c_v, c_u$ and $c_x$, and let $w_y$ be the radical center of the triple $\{c_v, c_u, c_y\}$. Let $z_u, z_v$ be the centers of $c_u, c_v$, respectively. Finally, for a vertex $v$, let $R_v$ denote the radius of the circle $c_v$. The sum of the angles at $v \in P$ is obtained by adding the angles formed by the edges of the contact graph of $P$ emanating from $z_v$. 
Stephenson’s conductance of an edge is defined by [see also Definition 3.8 and Eq. (A.15)]:

$$c(e) = c(u, v) = \frac{|w_x - w_y|}{|z_u - z_v|}.$$  \hfill (2.1)

It is illuminating to give a probabilistic interpretation to this quantity. Stephenson’s main idea was to chase angle changes at the centers of the circles, as radii change while maintaining (new) disk packing. Given a Euclidean circle packing, the effect of a small increase in the radius of one of the circles, say $R_v$, is that the sum of the angles at $v$ decreases, while the angle sums at the neighboring vertices $\{v_1, v_2, \ldots, v_k\}$ increase. Some of the angle “distributed” by $v$ arrives at $v_j$ and must be passed along in order to keep a packing at $v_j$. Hence, $R_{v_j}$ has to be adjusted and we need to keep track of the angle changes of its neighbors, and so forth.

In Euclidean geometry, the angles of any triangle add up to $\pi$, so angles in this process will never get lost. In other words, the total angle leaving one vertex must be divided into portions and then distributed as angles arriving to its neighbors. This movement can be expressed as a Markov process, where the transition probability from $v$ to $v_j$ is the proportion of a decrease in the sum of the angles at $v$ that becomes an increase in the sum of the angles at $v_j$. In this Markov process, the random walkers are the quantities of angles moving from one vertex to another. Thus, for a specific neighbor $u = v_j$, the amount of angle arriving at $\psi_u$ is given by $\frac{d\psi_u}{dR_v}$. It turns out that the transition probability from $v$ to $u$ as described above is given by

$$\bar{\rho}(v, u) = \frac{\frac{d\psi_u}{dR_v}}{\sum_{j=1}^{k} \frac{d\psi_{v_j}}{dR_{v_j}}}. \hfill (2.2)$$
Also, for a vertex \( v \in K \), we let

\[
\rho(v, u) = \frac{c(v, u)}{\sum_{u \sim v} c(v, u)}.
\] (2.3)

It is remarkable that in 2005 (see [54, Section 18.5]) Stephenson showed that equality holds between these two Markov transitions, that is,

\[
\rho(v, u) = \bar{\rho}(v, u), \quad u \sim v.
\] (2.4)

3 Smooth harmonic conjugate functions and their combinatorial counterparts

This section entails several key definitions and constructions. In the first subsection, we collect a few classical PDE existence results that go back to Poincaré and Lesbegue. In the second subsection, we will assume that \( A \) is a fixed, planar, polygonal annulus endowed with a triangulation \( T \). We will write \( \partial A = E_1 \cup E_2 \) where \( E_1 \) denotes the outer boundary component.

After recalling the definitions of the combinatorial Laplacian and the normal derivative, we will turn to define the class of discrete, asymptotically harmonic functions. (This class includes discrete harmonic functions.) The main goal of this section is to define a conjugate function to any function in this class (see Definition 3.9). One interesting feature of the conjugate function is that, in general, and unlike the smooth category, it is not harmonic.

3.1 Strong solutions of the Laplace equation and smooth harmonic conjugate functions

The solutions of the Laplace equation, harmonic functions, have a foundational role in various areas of mathematics. In this paper, we will apply known connections between harmonic functions and conformal maps defined on \( \Omega \). Furthermore, we will later on use an approximation scheme of the solution in our construction of a combinatorial analogue of the harmonic conjugate function. Let \( \Omega \) be a bounded, planar domain and assume that \( u \in C^2(\Omega) \cap C(\bar{\Omega}) \) is the strong solution of the Dirichlet boundary value problem for the Laplace equation with non-homogeneous boundary conditions

\[
\begin{aligned}
\Delta u &= 0 \text{ in } \Omega, \\
\quad u &= h \text{ on } \partial \Omega,
\end{aligned}
\] (3.1)

where \( h \in C(\partial \Omega) \), or more generally is the trace of \( \tilde{h} \in H^1(\Omega) \).

The study of the existence of strong solutions of Dirichlet boundary value type problems has an impressive history. Poincaré introduced the notion of barriers, and their importance was further recognized later by Lebesgue. A function \( w \in C^0(\Omega) \)
is called \textit{super-harmonic} in $\Omega$, if for any closed region $\Omega' \subset \Omega$, and any harmonic function $u$ in the interior of $\Omega'$, whenever the inequality
\begin{equation}
    w \geq u
\end{equation}
holds on the boundary of $\Omega'$, it also holds in the interior of $\Omega'$.

Let $\xi$ be a point in $\partial \Omega$, then a $C^0(\overline{\Omega})$ function $w = w_\xi$ is called a \textit{barrier} at $\xi$ relative to $\Omega$. If $w$ is super-harmonic in $\Omega$, it approaches 0 at $\xi$, and outside of any sphere about $\xi$, it has a positive lower bound in $\Omega$. Two profound consequences of the existence of a barrier are the following.

\textbf{Theorem 3.1} [39, Theorem III, page 327] \textit{A necessary and sufficient condition that the Dirichlet problem for $\Omega$ is solvable for arbitrary assigned continuous boundary values is that a barrier for $\Omega$ exists at every point in $\partial \Omega$.}

It is therefore important to understand which domains in the Euclidean plane satisfy the hypothesis of Theorem 3.1. Indeed, general sufficient conditions can be described in terms of local properties of the boundary (see, for instance, [60, Proposition 5.13]).

\textbf{Theorem 3.2} (Lebesgue) \textit{The Dirichlet boundary value problem (3.1) is solvable for arbitrary assigned continuous boundary values if every component of the complement of the domain consists of more than a single point.}

For the applications of this paper, the following corollary is essential.

\textbf{Corollary 3.3} \textit{Let $\Omega$ be a Jordan domain, then the Dirichlet boundary problem (3.1) is solvable in $\Omega$ for arbitrary continuous boundary values.}

The (strong) maximum principle (see, for instance, [13]) implies that a strong solution is unique. Therefore, in the special case studied in the this paper, where $\Omega = \mathcal{A}$ is a planar annulus (with polygonal or even continuous boundary), we make the following:

\textbf{Definition 3.4} We call $u \in C^2(\mathcal{A}) \cap C^0(\overline{\mathcal{A}})$ the strong solution of the Dirichlet boundary value problem of the Laplace equation, if
\begin{align*}
    \triangle u &= 0 \text{ in } \mathcal{A}, \\
    u &= 1 \text{ on } E_1, \text{ and } u = 0 \text{ on } E_2. 
\end{align*}

We end this subsection by recalling the following definition which is valid for any harmonic function.

\textbf{Definition 3.5} [A smooth harmonic conjugate (see, for instance, [45, Chapter 1.9])] Let $(x_0, y_0)$ be a point in $\mathcal{A}$, and let $(x, y)$ in $\mathcal{A}$ be an arbitrary point. Let $\gamma$ be a simple, piecewise smooth curve joining $(x_0, y_0)$ to $(x, y)$ in $\mathcal{A}$. Let $\beta$ be any simple, closed, counterclockwise-oriented, piecewise smooth curve in $\mathcal{A}$ whose winding number is equal to 1. Furthermore, let $s$ denote the arc-length parameter of these curves, and let $\hat{n}$ denote a unit normal pointing to the right of the tangents to these curves.
A (multivalued) harmonic conjugate of \( u \) is defined by
\[
u^*(x, y) = u^*(x_0, y_0) + \int_y \frac{\partial u}{\partial n} \, ds,
\]
where \( u^*(x_0, y_0) \) is some arbitrary fixed real constant, and the period of \( u^* \) is defined by
\[
\text{period}(u^*) = \int_\beta \frac{\partial u}{\partial n} \, ds.
\]

**Remark 3.6** It is well known that a smooth harmonic conjugate \( u^* \) is defined up to a constant, i.e., an assigned value at a point in the annulus. Furthermore, the function values at any point differ by integral multiples of its period, i.e., \( u^* \) is multivalued.

### 3.2 Discrete harmonic and asymptotically harmonic functions, and their conjugates

We now turn to defining a combinatorial function analogous to \( u^* \). We will start with some notation and definitions from the subject of discrete harmonic analysis that will be used throughout the rest of this paper (see, for instance, [7] or [36, Section 1.1]). Let \( \Gamma = (V, E, c) \) be a planar finite network; that is, a planar, simple, and finite connected graph with vertex set \( V \) and edge set \( E \), where each edge \( (x, y) \in E \) is assigned a conductance \( c(x, y) > 0 \). Let \( \mathcal{P}(V) \) denote the set of nonnegative functions on \( V \). Given \( F \subset V \), we denote by \( F^c \) its complement in \( V \). Set \( \mathcal{P}(F) = \{ u \in \mathcal{P}(V) : S(u) \subset F \} \), where \( S(u) = \{ x \in V : u(x) \neq 0 \} \). The set \( \delta F = \{ x \in F^c : (x, y) \in E \text{ for some } y \in F \} \) is called the vertex boundary of \( F \). Let \( \tilde{F} = F \cup \delta F \), and let \( \tilde{E} = \{ (x, y) \in E : x \in F \} \). Let \( \tilde{\Gamma}(F) = (\tilde{F}, \tilde{E}, \tilde{c}) \) be the network such that \( \tilde{c} \) is the restriction of \( c \) to \( \tilde{E} \). We write \( x \sim y \) if \( (x, y) \in \tilde{E} \), \( y \) is called a neighbor of \( x \), and we let \( N_x \) denote the cardinality of the set of neighbors of \( x \). The following operators are discrete analogues of classical notions in continuous potential theory (see, for instance, [14,22]).

**Definition 3.7** Let \( u \in \mathcal{P}(\tilde{F}) \). Then for \( x \in F \), the function
\[
\Delta u(x) = \sum_{y \sim x} c(x, y) (u(x) - u(y))
\]
is called the Laplacian of \( u \) at \( x \). For \( x \in \delta(F) \), let \( \{y_1, y_2, \ldots, y_m\} \subset F \) be its neighbors.

The normal derivative of \( u \) at a point \( x \in \delta F \) with respect to a set \( F \) is defined by
\[
\frac{\partial u}{\partial n}(F)(x) = \sum_{y \sim x, y \in F} c(x, y)(u(x) - u(y)).
\]

Finally, \( u \in \mathcal{P}(\tilde{F}) \) is called discrete harmonic in \( F \subset V \) if \( \Delta u(x) = 0 \), for all \( x \in F \).
We will now turn a triangulation of a polygonal domain into a finite network endowed with geometrically chosen conductances. The choice of the conductances depends on an interesting relation between the given triangulation and its dual complex. These conductances are identical to Stephenson’s [see (2.1)]; however, in this paper they are motivated by a scheme of approximating flux of smooth functions (see the next section) and the finite element method (see “Appendix A.2”).

Let $T$ be a triangulation of a polygonal domain $\Omega$. The induced control volumes, or the Voronoi cells which we will associate with a triangulation $T$ are defined as follows. For each triangle $T \in T$, let $c_T$ denote the circumcenter of $T$, which by definition is the intersection point of the perpendicular bisectors of the edges. We join $c_T'$ to $c_T$ by a segment $[c_T', c_T]$ whenever $T$ and $T'$ share an edge. This procedure divides each (interior) triangle $T$ into three quadrilaterals and induces a new decomposition of $\Omega$.

The star of a vertex $x \in T$ is defined as the union of all edges and triangles in $T$ that contain $x$ and will be denoted by $\text{Star}(x)$. The control volume $\Omega_x$ of a vertex $x \in T$ is defined to be the star of $x$ in this new decomposition (Fig. 2).

Let $\{T_\rho\}_{\rho > 0}$ be a family of $\tau$-quasi-uniform triangulations of $\Omega$ (cf. Definition A.3). Let $V_\rho(T)$ denote the set of vertices of $T \in T_\rho$, and let $V_\rho^0(T_\rho) = \bigcup_{T \in T_\rho} V_\rho(T)$, enumerated by $\{x^0_1, x^0_2, \ldots, x^0_{M(\rho)}\}$. Each $\Omega_x$ is an open, simply connected, and polygonally bounded set. Its boundary, $\partial\Omega_x$, consists of finitely many (straight) line segments $\Gamma_{i,j} = \partial\Omega_{x_i} \cap \partial\Omega_{x_j}, j = 1, \ldots, n_i$, where $n_i$ is the number of vertices adjacent to $x_i$; note that along each $\Gamma_{i,j}$ the normal $\hat{n}_i|\Gamma_{i,j} = \hat{n}_{i,j}$ is constant.

**Definition 3.8** Let $m(i,j)$ denote the length of $\Gamma_{i,j}$, and let $d_{ij} = |x_i - x_j|$ denote the Euclidean distance between $x_i$ and $x_j$. Then the conductance of the edge $[x_i, x_j]$ is defined by

$$c[x_i, x_j] = \frac{m(i,j)}{d_{ij}}. \quad (3.8)$$

Hence, $m(i,j)$ is equal to $|c_T - c_{T'}|$, where $T$ and $T'$ are the (only) two triangles that $\Gamma_{i,j}$ intersects. Given such a triangulation $T$ of $A$, following [26, Chapter 2], for each
one of its Voronoi cells $\Omega_i$ which is centered at $x_i \in T^{(0)}$, we define two quantities which are determined by $T$:

$$
\lambda_i = \lambda \frac{m_{(i,j)}}{\Omega_i} \left( \max_{j \in N_{x_i}} m_{(i,j)} \right)^{1/2} \quad \text{and} \quad \lambda = \max_{x_i \in T^{(0)}} \lambda_i, \quad (3.9)
$$

where $l(\cdot)$ denotes Euclidean length.

In this paper, we will assume the following.

(V0) Every triangulation $T$ is $\tau$-quasi-uniform for some fixed $\tau > 0$ and consists exclusively of nonobtuse triangles.

It is well known (see, for instance, [63]) that the $\tau$-quasi-uniform condition is equivalent to Zlámal’s condition: there exists a positive constant, $\theta_{\min}$, such that, for all $T \in \bigcup_{\rho} T_{\rho}$, and for any angle $\theta_T$ of $T$, we have

$$
\theta_{\min} \leq \theta_T. \quad (3.10)
$$

Assumption (V0) also implies that $T$ is a Delaunay triangulation, i.e., no point in the vertex set of $T$ lies inside the circumcircle of any triangle in $T$, and the corresponding Voronoi diagrams can be constructed by means of the perpendicular bisectors of the triangles’ edges (see, for instance, [3, Theorem 6.5]).

We now define a class of combinatorial functions that will naturally appear in the next section. The combinatorial counterpart of the real part of the uniformizing mapping of an annulus belongs to this class of discrete functions.

**Definition 3.9** Let $\alpha \in \mathbb{R}$ be a positive constant. Let $T$ be a triangulation of $A$, with Voronoi cells $\{\Omega_i\}_{i \in I}$. A function $g : T^{(0)} \rightarrow \mathbb{R}$ is said to be asymptotically harmonic of order $\alpha$ with respect to conductance constants $\{c_{(i,j)} = c(x_i, x_j)\}$, if there exists a nonnegative constant, $d$, such that

$$
|\Delta g(x_i)| = \left| \sum_{j \in N_{x_i}} c_{(i,j)} (g(x_j) - g(x_i)) \right| \leq d \lambda^\alpha, \quad \text{for all } x_i \in T^{(0)}. \quad (3.11)
$$

Note that the case $d = 0$ corresponds to $g$ being discrete harmonic (Fig. 3).

The following lemma provides an estimate for the summation of the normal derivative of $g$ along special closed curves in $T^{(1)}$. This sum encapsulates the discrete flux of $g$ through the boundary of the union of those Voronoi cells which such a closed curve encloses.

**Lemma 3.10** (Asymptotic flux estimate) Let $g : T^{(0)} \rightarrow \mathbb{R}$ be a discrete, harmonic or asymptotically harmonic of order $\alpha$, with respect to conductance constants $\{c_{(i,j)}\}$. Then, for any homotopically trivial (in $A$), closed path $\gamma \subset T^{(1)}$ which contains an integer number of Voronoi cells $\Omega_{x_i}$, $x_i \in T^{(0)}$, we have

$$
\sum_{x \in \gamma} \frac{\partial g}{\partial n}(x) = 0, \quad \text{if } g \text{ is harmonic.} \quad (3.12)
$$
Furthermore, if $g$ is asymptotically harmonic or order $\alpha$, then there exists a positive constant, $D$, such that
\[ \sum_{x \in \gamma} \frac{\partial g}{\partial n}(x) \leq D \lambda^\alpha. \] (3.13)

**Proof** Let $\Omega_m = \bigcup_{i=1}^m \Omega_i$, be the maximal collection of control volumes enclosed in $\gamma$, and let $E_m$ be those edges of $T^{(1)}$ that lie in the interior of the bounded region enclosed by $\gamma$. The first Green identity (see, for instance, [7, Proposition 3.1]) implies that for $u, v \in \mathcal{P}(\Omega_m)$, we have that
\[ \sum_{[i,j] \in E_m} c_{(i,j)} (u(i) - u(j)) (v(i) - v(j)) = \sum_{x \in \Omega_m \cap T^{(0)}} \Delta u(x) v(x) + \sum_{y \in \gamma} \frac{\partial u}{\partial n}(\Omega_m)(y) v(y). \] (3.14)

We now let $v \equiv 1$ in the above equality and obtain
\[ 0 = \sum_{i=1}^m \Delta u(x_i) + \sum_{y \in \gamma} \frac{\partial u}{\partial n}(\Omega_m)(y). \] (3.15)
It therefore follows, by the definition of the combinatorial Laplacian, that

$$0 = \sum_{i=1}^{m} \sum_{j \in N_i} c(i,j) \left( u(j) - u(i) \right) + \sum_{y \in \gamma} \frac{\partial u}{\partial n}(\Omega_m)(y). \quad (3.16)$$

Hence, the first assertion of the lemma readily follows; the second assertion follows with $D = D(d, m)$. \hfill \Box

With the notation of the lemma, the following corollary easily follows.

**Corollary 3.11 (Asymptotic path independence)** Let $\gamma_1$ and $\gamma_2$ be two simple paths in $T^{(1)} \subset A$ joining two vertices $x_1, x_2 \in T^{(0)}$, such that the path $\gamma_2^{-1} \circ \gamma_1$ is trivial in $\pi_1(A)$, and contains an integer number of control volumes $\Omega_{x_i}$. Then, if $g$ is harmonic we have

$$\sum_{x \in \gamma_1} \frac{\partial g}{\partial n}(x) - \sum_{x \in \gamma_2} \frac{\partial g}{\partial n}(x) = 0. \quad (3.17)$$

Furthermore, if $g$ is asymptotically harmonic or order $\alpha$, then

$$\left| \sum_{x \in \gamma_1} \frac{\partial g}{\partial n}(x) - \sum_{x \in \gamma_2} \frac{\partial g}{\partial n}(x) \right| \leq D \lambda^\alpha. \quad (3.18)$$

Let $g$ be a discrete, harmonic or asymptotically harmonic function. Inspired by the classical construction of the harmonic conjugate function as recalled in Definition 3.5, we will define a combinatorial conjugate to $g$ using discrete sums, i.e., using discrete fluxes. To this end, we will need to define a special class of paths in $T^{(1)}$. Thereafter, by summing a generalized version of the normal derivative of $g$, along a path from this class, the combinatorial conjugate function of $g$ will be defined firstly at the vertices of the Voronoi cells of $T$. In the next section, it will be proved that the imaginary part of a uniformizing map of a given annulus can be approximated by a sequence of combinatorial conjugate functions of $g$.

We let $\Lambda$ denote the union of all Voronoi cells of a given $T$. An interior cell is one such that its vertex boundary is disjoint form $\partial A$. We now make the following:

**Definition 3.12 (Flux fellow paths)** Let $\omega_0$ be a fixed vertex in an interior Voronoi cell, and let $\omega$ be any vertex in an interior cell of $\Lambda$. Let $\gamma_\Lambda = [\omega_0, \ldots, \omega_k = \omega]$ be a simple, piecewise linear curve in $\Lambda^{(1)}$ joining $\omega_0$ to $\omega$, whose trace is disjoint from $\partial A$. For each $[\omega_i, \omega_{i+1}]$, $i = 0, \ldots, k - 1$, let $x_i$ be the vertex in $T^{(0)}$ on the unique edge intersecting $[\omega_i, \omega_{i+1}]$, and which is to the right of $[\omega_i, \omega_{i+1}]$. Then $\gamma_T = [x_0, \ldots, x_{k-1}] \subset T^{(1)}$ will be called the flux fellow path of $\gamma_\Lambda$ (see Fig. 4).

**Remark 3.13** The discussion preceding condition (V0) grants us that $\gamma_T$ is indeed a path in $T^{(1)}$ (which is disjoint from $\partial A$); we orient each edge in the paths $\gamma_\Lambda, \gamma_T$ according to an increasing order of its vertices.
Note that $\gamma_T$ is uniquely determined only after a choice of $\gamma_\Lambda$ was made. However, vertices of $\gamma_T$ do not belong to the vertex boundary of any naturally defined domain in $T^{(0)}$. In light of the coming applications, we will now extend the notion of the discrete normal derivative [see (3.7) in Definition 3.7]. The definition of the combinatorial conjugate function will utilize this generalized version.

In the definition below, we will abuse notation and use the notation for normal derivative that appeared in Eq. (3.7).

**Definition 3.14 (Flux through edges)** For any vertex $y \in \gamma_T$, we define

$$\frac{\partial g}{\partial n}(\gamma_\Lambda, \gamma_T)(y) = \sum_{x \sim y} c(x, y)(g(x) - g(y)),$$

where the sum is taken over all those vertices $x \in T^{(0)}$ which are adjacent to $y$ along an edge which intersects $\gamma_\Lambda$.

We now make a combinatorial definition which imitates the smooth one (Definition 3.5).

**Definition 3.15 (A combinatorial conjugate)** Let $T$ be a triangulation of $\mathcal{A}$, and let $\Lambda$ denote the union of all Voronoi cells of $T$. Let $\omega_0$ be a fixed vertex in an interior cell of $\Lambda$, and let $\omega$ be any vertex of an interior cell $\Lambda$. Let $\gamma_\Lambda \subset \Lambda^{(1)}$ be a simple, piecewise linear curve joining $\omega_0$ to $\omega$ whose trace is disjoint from $\partial \mathcal{A}$. Let $\gamma_T \subset T^{(1)}$ be the flux fellow path of $\gamma_\Lambda$.
(i) Let \( g \) be a discrete, harmonic or asymptotically harmonic function of order \( \alpha \). Then, for every \( \omega \in \Lambda \), a (multivalued) combinatorial conjugate of \( g \) is defined by

\[
\bar{g}^\ast(\omega) = \bar{g}^\ast(\omega_0) + \sum_{y \in \gamma_T} \frac{\partial g}{\partial n}(\gamma_T, y) = \sum_{y \in \gamma_T} \bar{\partial} g(\gamma_T, y).
\]

where \( \bar{g}^\ast(\omega_0) \) is some arbitrary, fixed real constant.

By choosing a vertex in each 2-cell in \( \Lambda(2) \) and drawing diagonals to its other vertices, this cell is divided into triangles with vertices in \( \Lambda(0) \) and disjoint interiors. We then extend \( g^\ast \) affinely over edges in \( \Lambda(1) \) and over triangles in \( \Lambda(2) \). (By abuse of notation, the extended function will also be called a combinatorial conjugate of \( g \).)

(ii) Let \( \alpha/\Lambda \) be any simple, counterclockwise-oriented, closed curve in \( \Lambda \) whose winding number is equal to 1. The period of \( \bar{g}^\ast \) is defined by

\[
\text{period}(\bar{g}^\ast) = \sum_{\xi \in \alpha_T} \frac{\partial g}{\partial n}(\xi).
\]

Remark 3.16 It follows from Corollary 3.11 that if \( g \) is discrete harmonic (i) and (ii) are independent of the choices of \( \gamma_{\Lambda} \) and \( \gamma_T \). If \( g \) is discrete and asymptotic harmonic of order \( \alpha \), then (i) and (ii) hold up to (in absolute value) a factor of at most \( D\lambda^\alpha \). Furthermore, combinatorial provisions analogous to those in Remark 3.6 hold for \( \bar{g}^\ast \).

Remark 3.17 The search for discrete analogues of conformal maps has a long and rich history. We refer to [12, Section 2] and [43] for excellent recent accounts. We should also mention that a search for a combinatorial Hodge star operator has recently gained much attention and is closely related to the construction of a harmonic conjugate function. We refer the reader to [37] and to [46,47] for further details, examples, and applications of such combinatorial operators.

4 Uniformization of a planar annulus

In this section, we prove the main theorem of this paper, Theorem 4.7 which provides a discrete scheme of approximation of the uniformizing map of a polygonal annulus. Thereafter, we will prove that the hypotheses “polygonal boundary” in this theorem can be relaxed to “continuous boundary.”

We keep the notation of the previous sections and appendices. Let \( \mathcal{A} \) be endowed with a family of \( \tau \)-quasi-uniform triangulations \( \{T_{\rho_n}\} \) (cf. Definition A.3) such that \( \rho_n \to 0 \), as \( n \to \infty \). For each \( T_{\rho_n} \), let the corresponding family of Voronoi cells be denoted by \( \{\Omega_n = \Omega_{\rho_n}\} \) (see the discussion proceeding Fig. 2). We let \( V_{\rho}(T) \) denote the set of vertices of a triangle \( T \in T_{\rho}^{(2)} \), and let \( V_{\rho}^{(0)}(T_{\rho}) \) denote the set of interior vertices of \( V_{\rho}(T_{\rho}) = \bigcup_{T \in T_{\rho}} V_{\rho}(T) \).

For each vertex \( x \), recall that \( N_x \) denotes the set of neighboring (in \( T_{\rho}^{(0)} \) ) vertices of \( x \). In addition to requiring that each triangulation is quasi-uniform, henceforth in this paper, we will assume the existence of a constant \( \tau_0 \) such that for all \( \rho_n < \tau_0 \), the following hold:
(V1) The cardinality $N_x$ of each vertex $x \in T^{(0)}_{\rho_n}$ remains uniformly bounded, that is,
\[
\max_x \{ \text{card}(N_x) \} \leq m_* \text{ for some } m_* \in \mathbb{N};
\]

(V2) Each point $x_{i,j} = [x_i, x_j] \cap \Gamma_{i,j}$ is the middle point of the segment $\Gamma_{i,j}$.

### 4.1 Stephenson's conductance constants from a flux perspective

In this section, we will continue to assume that $A$ is a fixed polygonal annulus. We will construct a sequence of mappings, obtained via a refined sequence of quasi-uniform triangulations and conductance constants along edges according to (3.8), from the interior of $A$ onto the interior of a concentric Euclidean annulus. The image annulus is determined [see Eq. (4.10)] by the solution of a specific smooth boundary value problem defined on the domain: Laplace’s equation with non-homogeneous boundary values. Theorem 4.7 demonstrates that the sequence converges uniformly on compact subsets to a conformal homeomorphism.

In the proof of Theorem 4.7, we will need to consider a Dirichlet boundary value problem for the Laplace equation with prescribed boundary data as formulated in (3.3). In fact, an approximation scheme for this type of boundary value problem is obtained through the analysis of a naturally defined different boundary value problem, i.e., one with prescribed Poisson data and homogeneous boundary condition.

In order to get the necessary analysis in place, let $h$ be the continuous function defined on $\partial A$ by setting $h|_{E_1} = 1$ and $h|_{E_2} = 0$, and (4.1) let $\tilde{h} \in C^2(A) \cap C^0(\bar{A})$ be an extension of $h$ to the interior of $A$ with $\Delta \tilde{h} \neq 0$. Recall that the existence of such an extension is a consequence of Whitney’s seminal work [61].

We now define a Poisson boundary value problem, which is naturally associated with the Laplace problem (3.3) we wish to solve, by
\[
\begin{cases}
\Delta \tilde{u} = -\Delta \tilde{h}, & \text{in } A \\
\tilde{u} = 0, & \text{on } \partial A.
\end{cases}
\] (4.2)

**Remark 4.1** The existence and uniqueness of a strong solution to (4.2) follow (for instance) from Corollary 3.3, by setting $\tilde{u} = u - \tilde{h}$, where $u$ is the strong solution of (3.1).

### 4.2 The convergence of the piecewise linear approximations to the strong solution

In this section, we will recall one of the main convergence results in a classical paper by Schatz and Wahlbin [50]. This foundational quantitative result, derived explicitly by
the finite element method (see “Appendix A.2”), describes the rate of approximation of particular combination of piecewise linear maps to the smooth solution of a Poisson boundary value problem with homogeneous boundary values.

For the applications of this paper, it is necessary to consider non-convex polygonal domains. In order to approximate a given Jordan domain, which in general is not convex, we will construct a sequence of necessarily non-convex polygonal domains where each domain is triangulated by acute triangles, and each triangulation has a uniform upper and lower bounds on their largest and smallest angles, respectively. However, due to the presence of corner singularities of vertex angles that are bigger than \( \pi \), the \( L_\infty \) error analysis of the approximation provided by the finite element is quite subtle (see, for instance, the monograph [25] for treatment of convergence in other norms).

Let \( \Omega \) be a bounded, (possibly) non-convex, polygonal domain. Let \( \partial \Omega \) denote the boundary of \( \Omega \). Therefore, \( \partial \Omega \) consists of a finite number of straight line segments meeting at vertices \( v_j, j = 1, \ldots, M_2 \), of interior angles \( 0 < \alpha_1 \leq \cdots \leq \alpha_{M_2} < 2\pi \); let \( \beta_j = \pi/\alpha_j \). We let \( \Upsilon_j, j = 1, \ldots, M_2 \), denote the intersection of \( \Omega \) with a disk centered at \( v_j \) and such that \( \Upsilon_j \) contains no other vertex, and define \( \Upsilon_0 = \Omega \setminus \bigcup_{j=1}^{M_2} \Upsilon_j \). Then, it is well known that the solution \( u \) of the boundary value problem defined in (A.1) is not always in \( H^2(\Omega) \) (see, for instance, [25, Section 2]). However, for every \( \epsilon > 0 \), \( u \) always belongs to a fractional order Sobolev space \( H^{1+\beta_{M_2}-\epsilon}(\Upsilon_j) \) or \( C^{\beta_{M_2}-\epsilon}(\bar{\Upsilon}_j) \), and \( u \in C^\infty(\Upsilon_0) \) (cf. [50, page 74]).

The following foundational result was obtained by Schatz and Wahlbin in the 1970s. It is the main analytical result which will be used in this paper.

**Theorem 4.2** [50, Theorem 4.1] Let \( \epsilon > 0 \) be given. Let \( \tilde{u} \) and \( \tilde{u}_\rho \) be the solutions of (A.1) and (A.11), respectively, with \( f \in L_p, \ p > 1 \). Then there exists a constant \( c = c(f, \epsilon) \) such that for \( \rho \) sufficiently small

\[
\|\tilde{u} - \tilde{u}_\rho\|_{L_\infty(\Upsilon_0)} \leq c\rho^{\min(2, 2\beta_{M_2})-\epsilon}.
\]

Since the polygonal domains in the applications of this paper are not convex, \( 1/2 < \beta_{M_2} \), hence, \( \min(2, 2\beta_{M_2}) = 2\beta_{M_2} > 1 \).

**Remark 4.3** There is another interesting part to this theorem which provides an \( L_\infty \) estimate inside \( \Upsilon_j, j = 1, \ldots, M_2 \). (We will not use this part in this paper.)

Finally, let \( u \) be a solution of (3.3); hence, we may write \( u = \tilde{u} + \tilde{h} \). Thus, since with \( \tilde{u} \) we are in the framework of (A.1), we can proceed with

**Definition 4.4** Let \( \tilde{u} \) and \( \tilde{u}_n = \tilde{u}_{\rho_n} \) be the solutions of (4.2) and (A.11) with \( f = -\Delta \tilde{h} \), respectively. We will also assume that for every \( n > 0 \), \( \tilde{u}_n \) is presented by a linear combination of the basis elements in \( \mathbb{V}_{0, T_{\rho_n}} \), as described in (A.12).

We also need a natural way to discretize \( \tilde{h} \). Hence, let us denote the projection of \( \tilde{h} \) on \( T_{\rho_n}^{(0)} \) by \( \Pi_n(\tilde{h}) \), that is,

\[
\Pi_n(\tilde{h})(x) = \tilde{h}(x), \quad \text{for every } x \in T_{\rho_n}^{(0)},
\]
and then extend affinely over edges and triangles.

As the final preparation for the proof of our main theorem, let us recall a lemma due to Grossmann, Roos, and Stynes. This important lemma provides an approximation of the integral of the Laplacian of a smooth function, given for instance by the right-hand side of (4.2), by a discrete quantity—a finite difference expression which utilizes Stephenson’s constants. Recall that we have let \( m_{i,j} \) denote the length of \( \Gamma_{i,j} \), and \( d_{ij} = |x_i - x_j| \) denote the Euclidean distance between \( x_i \) and \( x_j \) (see Definition 3.8).

The conductance of the edge \([x_i, x_j]\) is then defined by

\[
  c[x_i, x_j] = \frac{m_{i,j}}{d_{ij}}.
\]

**Lemma 4.5** ([26, Lemma 2.63]) Let \( \Omega \subset \mathbb{R}^2 \) be a convex polygon. Assume that conditions (V1) and (V2) hold. Assume that the solution of the Poisson boundary value problem with (possible) non-homogenous boundary data

\[
\begin{aligned}
  &\Delta w = f, \text{ in } \Omega \\
  &w = g, \text{ on } \Gamma = \partial \Omega,
\end{aligned}
\]  

belongs to \( C^2(\bar{\Omega}) \). Then there exists some constant \( c = c(w, \Omega) \) such that

\[
\left| \sum_{x_j \sim x_i, j \neq i} \frac{m_{i,j}}{d_{ij}} (w(x_j) - w(x_i)) - \int_{\Omega_{x_i}} f \, dx \right| \leq c \lambda_i^3,
\]

for all interior vertices \( x_i \), and where \( \lambda_i \) is defined by (3.9).

Thus, this lemma provides an estimate for the discrete flux along the full boundary of one Voronoi cell of a solution of the boundary value problem (4.5). In the statement of this lemma, \( \Omega \) is assumed to be a convex polygon in \( \mathbb{R}^2 \). However, the proof remains valid even if the regularity assumption of the solution is only assumed to hold for any close, proper subset of \( \Omega \) with thick enough neighborhood; that is, if the subset and its neighborhood are still contained in \( \Omega \). This weaker regularity assumption will be used in the proof of Theorem 4.7, where we will also show how to choose an appropriate thick neighborhood. Assumptions (V1) and (V2) are critical to the proof of this Lemma.

**Remark 4.6** Equation (A.15) complements (4.6) in regard to the terms appearing in the conductances and exploits the connection to Stephenson’s conjecture (Conjecture 1.1) from the finite element perspective.

### 4.3 The main theorem

With the notation above, we now turn to the main theorem of this paper. In order to ease the notation, we will not distinguish between a map defined on the 0-skeleton of a triangulation and the affine extension of the map on edges and triangles. Finally, for every \( n \), let \( T_n = T_{pn} \).
Theorem 4.7 Let \( \{ T_n \} \) be a sequence of quasi-uniform triangulations of \( A \) of mesh size \( \rho_n \to 0 \) as \( n \to \infty \), and let the corresponding family of Voronoi cells of each \( T_n \) be denoted by \( \{ \Omega_n \} \). Assume in addition that \( \{ T_n \} \) satisfies conditions \((V1)\) and \((V2)\).

Let the conductance of each edge \( e \in T, T \in T_n^{(2)} \) be defined by

\[
c_n(e) = \frac{m^T(i,j).n}{d_{ij}.n}.
\] (4.7)

Let \( u \) and \( h \) be given in (3.3) and (4.1), respectively, and define [see Definition (4.4)]

\[
g_n = \tilde{u}_n + \Pi_n(\tilde{h}).
\] (4.8)

Then, as \( n \to \infty \) the following assertions hold:

(1) \( \| u - g_n \|_{L_\infty(A)} \to 0 \).

(2) On each proper, compact subset of \( A \), the \( g_n \)'s are asymptotically harmonic of order \( \alpha = 3 \).

(3) Let \( \tilde{g}_n^* \) denote a suitable normalized combinatorial conjugate of \( g_n \), and let \( \phi_n \) be the sequence of discrete mappings defined by extending affinely over \( \Omega_n \) the sequence of discrete mappings given by

\[
\phi_n(\omega) = \exp \left( \frac{2\pi}{\text{period}(\tilde{g}_n^*)} (g_n(\omega) + i \tilde{g}_n^*(\omega)) \right), \quad \omega \in A \cap \Omega_n^{(0)}.
\] (4.9)

Then a subsequence of \( \{ \phi_n \} \) converges uniformly on compact subsets of \( A \) to a conformal homeomorphism, denoted by \( \Psi_\mathcal{A} \), onto the interior of the concentric Euclidean annulus \( \mathcal{E}_A \), whose inner and outer radii are given by

\[
\{ R_1, R_2 \} = \left\{ 1, \exp \left( \frac{2\pi}{\text{period}(u^*)} \right) \right\}.
\] (4.10)

where \( u^* \) and \( \text{period}(u^*) \) are given in Definition 3.5.

Remark 4.8 By choosing conductance constants according to (4.7) for every \( \rho_n > 0 \), as predicted in Stephenson’s conjecture (see Conjecture 1.1), each \( T_{\rho_n} \) is turned into a finite electrical network; where for each \( n > 0 \), the homogeneous part of the induced potential function, \( \tilde{u}_n \) (see [53]), satisfies the system of equations described by (A.17). We remark that since for each \( \rho_n > 0 \), the values of \( u_n = u_{\rho_n} \) at the boundary vertices in \( \partial T_n^{(0)} \subset \partial \Omega \) are given, there is no need to specify conductance constants for edges that are contained in \( \partial \Omega \); or one can choose arbitrary values.

The proof is not short and will therefore be naturally divided into two parts. In the first part, assertions (1) and (2) will be proved. In the second and longer part, the proof of assertion (3), which depends on (1) and (2), will be given.

Proof The proofs of assertions (1) and (2). By letting \( f = -\Delta \tilde{h} \) in Theorem 4.2 (Schatz–Wahlbin [50, Theorem 4.1]), we know that for the approximation of \( \tilde{u} \) by \( \tilde{u}_n \)
[see (4.2)], the following estimate holds. Let \( \epsilon > 0 \) be chosen so that \( 2\beta M_2 - \epsilon = 1 + \epsilon_0 \) with \( \epsilon_0 > 0 \). Let \( \tilde{u} \) and \( \tilde{u}_\rho \) be the solutions of (A.1) and (A.11), respectively, with \( f \in L_p, \ p > 1 \). Since \( 1 > \beta M_2 > 1/2 \), the assertion of the theorem is that there exists a constant \( C = C(f, \epsilon) \) such that for \( \rho \) sufficiently small

\[
\|\tilde{u} - \tilde{u}_\rho\|_{L_\infty(\Gamma_0)} \leq C \rho^{\min(2, 2\beta M_2) - \epsilon} = C \rho^{1 + \epsilon_0}.
\] (4.11)

Hence, as \( \rho_n \to 0 \) we have

\[
\|\tilde{u} - \tilde{u}_n\|_{L_\infty(\Gamma_0)} \to 0.
\] (4.12)

Since \( \tilde{h} \) is sufficiently smooth in \( \Gamma_0 \), it is well known that there exists a constant \( C_1 = C_1(f, \Gamma_0) \) such that

\[
\|\tilde{h} - \tilde{\Pi}_n(h)\|_{L_\infty(\Gamma_0)} \leq C_1 \rho^2,
\] (4.13)

where \( \tilde{\Pi}_n(h) \) is the affine interpolation of \( h \) [see (4.4)]. Hence, as \( \rho_n \to 0 \) we have

\[
\|\tilde{h} - \tilde{\Pi}_n(h)\|_{L_\infty(\Gamma_0)} \to 0.
\] (4.14)

We now show that the \( g_n \)'s comprise our desired approximations to \( u \) - the strong solution of the smooth Dirichlet problem for the Laplace Eq. (3.3). Indeed, we have

\[
\|u - (\Pi_n(h) + \tilde{u}_n)\|_{L_\infty(\Gamma_0)} = \|u - \tilde{h} + \tilde{h} - (\tilde{u}_n + \Pi_n(h))\|_{L_\infty(\Gamma_0)}
\]
\[
= \|\tilde{u} + \tilde{h} - (\tilde{u}_n + \Pi_n(h))\|_{L_\infty(\Gamma_0)}
\]
\[
= \|((\tilde{u} - \tilde{u}_n) + (\tilde{h} - \Pi_n(h))\|_{L_\infty(\Gamma_0)}
\]
\[
\leq \|\tilde{u} - \tilde{u}_n\|_{L_\infty(\Gamma_0)} + \|\tilde{h} - \Pi_n(h)\|_{L_\infty(\Gamma_0)}.
\] (4.15)

Therefore, assertion (1) of the Theorem is proved by applying Eqs. (4.12) and (4.13), where, in fact, the rate of convergence is at least of the following order in \( \rho \):

\[
\|u - g_n\|_{L_\infty(\Gamma_0)} = \|u - (\Pi_n(h) + \tilde{u}_n)\|_{L_\infty(\Gamma_0)} \leq C_2 \rho^{1 + \epsilon_0},
\] (4.16)

for some constant \( C_2 = C_2(C, C_1) \).

We now continue and prove assertion (2) by showing that for all \( n \) large enough, each \( g_n \) is asymptotically harmonic of order 3. We already observed that \( \tilde{u} + \tilde{h} \) is a solution of (3.3)-the Dirichlet non-homogeneous boundary value problem for the Laplace equation with boundary values prescribed by \( h|\partial A \).

We now apply Lemma 4.5 with \( u = \tilde{u} + \tilde{h} \) and \( f = 0 \). It then follows that the following holds for all \( n > 0 \)

\[
\left| \sum_{x_j \sim x_i, j \neq i} \frac{m(i, j, n)}{d_{ij, n}} (u(x_j) - u(x_i)) \right| \leq C_3 \lambda_3^{3, n}, \text{ with } C_3 = C_3(u, \Gamma_0).
\] (4.17)

By applying the law of sines in Euclidean geometry and the existence of a uniform lower bound on the smallest angle [see (3.10)] in the sequence \( \{T_n\} \), it is easy to see...
that the conductances $c_n$ defined in (4.7) are uniformly bounded from above, with a bound depending only on $\theta_{\min}$. Hence, we finish the proof of (2) by applying the triangle inequality and assertion (1), in (4.16).

The proof of assertion (3). We now turn to prove the uniform convergence of the $\tilde{g}_n^*$'s, over compact subsets of $A$, to $u^*$ - the smooth harmonic conjugate of $u$. In particular, we will describe the normalization needed in assertion (3) of the theorem. Let $A^\kappa \subseteq Y_0 \subseteq A$ be a compact annulus with smooth boundary which is concentric with $A$, where $\kappa = \text{dist}(\partial A, \partial A^\kappa)$ is small. Let $\omega_0$ be a fixed point in $A^\kappa$, and we set $u^*(\omega_0) = 0$. Let $\omega$ be another fixed (for the moment) point in $A^\kappa$.

Let us choose $N$ large enough so that for all $n > N$ (i.e., $\rho_n$ small enough) there exists a triangulation $T_{\rho_n} \in \{T_n\}$ satisfying the following.

(V3) There exists a subset, $J'_n$, of the set of interior vertices $V^0_{\rho_n}(T_{\rho_n})$ such that the corresponding volume elements $\{\Omega_{x_i,\rho_n}\}_{x_i \in J'_n}$ are contained in $A^\kappa$, and the combinatorial one vertex neighborhood of this subset, when considered in $T_{\rho_n}^{(0)}$, is also contained in $A^\kappa$.

For each $n$ as above, following Definition 3.12 and the discussion following it, we choose one of the vertices of a cell $\Omega_{x_i,\rho_n}$ with $x_i \in J'_n$, which is closest to $\omega_0$. This vertex will be denoted by $\omega^n_0$. Let $\omega^n$ be any vertex in the union $\Lambda_{\rho_n} = \bigcup_{x_i \in J'_n} \Omega_{x_i,\rho_n}$ which is the closest to $\omega$. Let $\gamma_{[\omega^n_0,\omega^n]} = [\omega^n_0, \omega^n_0, \ldots, \omega^n_k, \omega^n]$ be a (piecewise linear) simple path in the one skeleton of $\Lambda_{\rho_n}$ which connects $\omega^n_0$ to $\omega^n$. Note that $k$ is also a function of $n$.

It then follows from Definition 3.5 and Remark 3.6 that the value of the smooth harmonic conjugate function $u^*$ with base at $\omega^n_0$ is given by

$$u^*(\omega) = \int_{\gamma_{\Lambda_{\rho_n}[\omega^n_0,\omega^n]}} \frac{\partial u^*}{\partial n} \, ds + \int_{\omega^n_0}^{\omega^n} \frac{\partial u^*}{\partial n} \, ds + \int_{\omega^n}^{\omega_0} \frac{\partial u^*}{\partial n} \, ds, \quad (4.18)$$

where the second integral is taken along any piecewise smooth curve joining $\omega_0$ to $\omega^n_0$, and the third integral is taken along any piecewise smooth curve joining $\omega^n$ to $\omega$.

We now follow the notation in Definition 3.12, and we let $\gamma_{T_{\rho_n}}$ denote the flux fellow path of $\gamma_{\Lambda_{\rho_n}[\omega^n_0,\omega^n]}$. Let us write $\gamma_{T_{\rho_n}} = [x^n_0, \ldots, x^n_k]$ and let $\tilde{g}_n^{*}(\omega^n_0) = 0$. Hence, by Definition 3.15, the value of the corresponding combinatorial conjugate of $g_n = g_{\rho_n}$ is defined at $\omega^n$ by

$$\tilde{g}_n^*(\omega^n) = \sum_{x \in \gamma_{T_{\rho_n}}} \frac{\partial g_n}{\partial n}(\gamma_{\Lambda_{\rho_n}, \gamma_{T_{\rho_n}}}(x)). \quad (4.19)$$

Note that as explained in Remark 3.16, this value may change by (up to) $D\Lambda^3_n$, if a different path connecting $\omega^n_0$ to $\omega^n$ and afterward a different flux fellow path are chosen. Recall that $D = D(n, m)$ with $m$ being the maximal number of Voronoi cells which belong to $\Lambda_{\rho_n}$ and are contained in $A^\kappa$. We will address this issue again after completing the following analysis.
We now turn to proving that as \( n \to \infty \),

\[
|u^*(\omega) - \tilde{g}_n^*(\omega)| \to 0
\]

(4.20)

uniformly in \( \mathcal{A}^\kappa \).

As \( n \to \infty, \cup_i \Omega_{x_i, \rho_n} \) with \( x_i \in J'_n \) comprises a dense subset of \( \mathcal{A}^\kappa \). In particular, by choosing \( \omega^0_n \to \omega_0 \) and \( \omega^m \to \omega \) as \( n \to \infty \), and due to the uniform continuity of the second and third integrals in (4.18) and the \( \tilde{g}_n^* \) in \( \mathcal{A}^\kappa \), we only need to bound from above the difference

\[
|u^*(\omega^n) - \tilde{g}_n^*(\omega^n)| = \left| \int_{\gamma_{\Lambda_n} [\omega^0_n, \omega^n]} \frac{\partial u}{\partial \hat{n}} \, ds - \sum_{x \in \gamma_{\Gamma_{\rho_n}}} \frac{\partial g_n}{\partial \hat{n}} (\gamma_{\Lambda_n}, \gamma_{\Gamma_{\rho_n}}(x)) \right|.
\]

(4.21)

To this end, following the definition of flux through edges, Definition (3.14), and the first assertion of the theorem, we will first show that we can replace each \( \frac{\partial g_n}{\partial \hat{n}} (\gamma_{\Lambda_n}, \gamma_{\Gamma_{\rho_n}}(x)) \) in the second integrand in (4.21), by \( m(i,j,n) \frac{\partial u}{\partial \hat{n}} (i,j)n (x_i^n, j) \).

As we noted before, \( u \in C^2(\mathcal{A}^\kappa) \), and therefore Equation (5.11) in [26, Chapter 2] shows that for \( x_i^n = x_i, \rho_n, x_j^n = x_j, \rho_n, \Gamma_{i,j} = [\omega^0, \omega^0] \) and \( n_{i,j} \) its outward pointing normal unit vector, and with \( \kappa_i, n = \kappa_i, \rho_n \) [see (3.9)], there exists a positive constant \( C_0 = C_0(u, \mathcal{A}^\kappa) \) so that

\[
\left| \frac{1}{d_{i,j,n}} \left( u(x_j^n) - u(x_i^n) \right) - \frac{\partial u}{\partial \hat{n}} (i,j)n (x_{i,j}^n) \right| \leq C_0 \kappa_i^2, \quad x_i \in J'_n, x_j \in N_{x_i, n}.
\]

(4.22)

where \( N_{x_i, n} \) denotes the set of neighbors of \( x_i^n \) in \( \Gamma_{\rho_n}^{(0)} \).

Let \( T \) be any triangle in a triangulation in \( \{ \Gamma_{\rho_n} \} \). As we argued in the proof of part (2), we have a uniform upper bound on the ratios \( m(i,j,n)/d_{i,j,n} \) in \( \{ \Gamma_{\rho_n} \} \), where the bound depends only on \( \theta_{\min} \). Hence, by applying the triangle inequality, multiplying Eq. (4.22) by \( m(i,j,n) \), and assertion (1), we obtain that the bound

\[
\left| \frac{m(i,j,n)}{d_{i,j,n}} \left( g_n(x_j^n) - g_n(x_i^n) \right) - m(i,j,n) \frac{\partial u}{\partial \hat{n}} (i,j)n (x_{i,j}^n) \right| \leq C_2 \rho_n^{1+\epsilon_0} + C_0 \kappa_i^3, \quad (4.23)
\]

which implies that the left-hand side of (4.23) converges to zero uniformly in \( \mathcal{A}^\kappa \).

For all \( x_i \in J'_n, x_j \in N_{x_i, n} \), let the continuous linear functional \( T_{i,j} = T_{i,j}^{n} \) on \( C^3(\Omega_{x_i}) \) defined by

\[
T_{i,j}(u) = \int_{\Gamma_{i,j}^{n}} \frac{\partial u}{\partial \hat{n}} (i,j)n \, ds - m(i,j,n) \frac{\partial u}{\partial \hat{n}} (i,j)n (x_{i,j}^n).
\]

(4.24)

The proof leading to Equation (5.15) in [26, Chapter 2] shows that the following estimate holds

\[
|T_{i,j}(u)| \leq C_4 \kappa_i^3, \quad \text{where } C_4 = C_4(u, \Omega_{x_i, \rho_n}).
\]

(4.25)
For \( W \subset \mathcal{A} \) and any two points \( a, b \in W \), we let \( D(a, b) \) denote the pseudo-distance on \( W \) defined as the infimum of the Euclidean lengths of curves in \( W \) that join \( a \) to \( b \). We then define the intrinsic diameter of \( W \) by

\[
\text{IDiam}(W) = \sup\{D(a, b) \mid a, b \in W\}. \tag{4.26}
\]

We will now estimate [where by (3.9) \( \lambda_n = \max_{x_i \in T_n^{(0)}} \lambda_{i,n} \)]

\[
\left| \int_{\gamma_{\Lambda_n, \omega_n}^{\rho_n, \omega_n}} \frac{\partial u}{\partial \hat{n}} \, ds - \sum_{i=0}^{k(n)} m(i, i+1, n) \frac{\partial u}{\partial \hat{n}} (x_{i,i+1}^n) \right| \\
= \left| \sum_{i=0}^{k(n)} \left( \int_{\omega_i, \omega_{i+1}^{\rho_n, \omega_n}} \frac{\partial u}{\partial \hat{n}} (i, i+1, n) \, ds - m(i, i+1, n) \frac{\partial u}{\partial \hat{n}} (i, i+1, n) (x_{i,i+1}^n) \right) \right| \\
\leq \sum_{i=0}^{k(n)} \left( \int_{\omega_i, \omega_{i+1}^{\rho_n, \omega_n}} \frac{\partial u}{\partial \hat{n}} (i, i+1, n) \, ds - m(i, i+1, n) \frac{\partial u}{\partial \hat{n}} (i, i+1, n) (x_{i,i+1}^n) \right) \\
\leq \frac{\text{IDiam}(\mathcal{A}^\epsilon)}{\lambda_n} c_2(u, \mathcal{A}^\epsilon) \lambda_{i,n}^3 \left( \text{since } k(n) \leq \frac{\text{IDiam}(\mathcal{A}^\epsilon)}{\lambda_n} \right) \\
\leq C_4(u, \mathcal{A}^\epsilon) \lambda_n^{-1} \lambda_{i,n}^3 \\
\leq C_4(u, \mathcal{A}^\epsilon) \lambda_n^2. \tag{4.27}
\]

It is evident that as \( n \to 0 \) we have that \( \lambda_n \to 0 \); hence, the left-hand side of (4.27) converges uniformly to zero in \( \mathcal{A}^\epsilon \). We are now able to obtain the desired upper bound for (4.21). Indeed,

\[
\left| \int_{\gamma_{\Lambda_n, \omega_n}^{\rho_n, \omega_n}} \frac{\partial u}{\partial \hat{n}} \, ds - \sum_{x \in \gamma_{T_n^{(0)}}} \frac{\partial g_n}{\partial n} (\gamma_{\Lambda_n, \omega_n}^{\rho_n, \gamma_{T_n^{(0)}}})(x) \right| \\
\leq \left| \int_{\gamma_{\Lambda_n, \omega_n}^{\rho_n, \omega_n}} \frac{\partial u}{\partial \hat{n}} \, ds - \sum_{i=0}^{k(n)} m(i, i+1, n) \frac{\partial u}{\partial \hat{n}} (i, i+1, n) (x_{i,i+1}^n) \right| \\
+ \sum_{i=0}^{k(n)} m(i, i+1, n) \frac{\partial u}{\partial \hat{n}} (i, i+1, n) (x_{i,i+1}^n) - \sum_{x \in \gamma_{T_n^{(0)}}} \frac{\partial g_n}{\partial n} (\gamma_{\Lambda, \omega_n}^{\rho_n, \gamma_{T_n^{(0)}}})(x) \right| . \tag{4.28}
\]

Since a bound on the first term in the left-hand side is established in (4.27), we only need to bound uniformly from above the second term in (4.28). To this end, using the estimate in (4.23) we can write
The uniform lower bound on the smallest angle implies that $\rho_n \leq C_5(\theta_{\min})\lambda_n$, hence we have

$$\frac{\text{IDiam}(A^e)}{\lambda_n} \left( C_2\rho_n^{-1}\epsilon_0 + C_0\lambda_n^{-3}\right) \leq K(u, A^e) \left( \rho_n^{\epsilon_0} + \lambda_n^2 \right).$$

(4.30)

To end this part of the argument [as we mentioned after (4.19)], we now assume that a different path connecting $\omega_n^0$ to $\omega^n$ is chosen. This will yield a different choice of a flux fellow path and a new normalized conjugate function. However, we may use the triangle inequality, estimate (4.27), and the fact that $n \leq \frac{\text{IDiam}(A^e)}{\lambda_n}$ to obtain the same kind of estimate for the new conjugate function.

We also need to prove that

$$\text{period}(\bar{g}_n^*) \rightarrow \text{period}(u^*).$$

(4.31)

To this end, let us choose a point $P_0$ in $A^e$, and let $\beta$ and $\text{period}(u^*)$ be given according to Definition 3.5. Furthermore, let $p_n \in \Lambda_{\rho_n}$ be chosen so that $p_n \rightarrow P_0$. Let $\gamma_{T_n}$ be a closed curve in $\Lambda_n^{(1)}$, based at $p_n$ according to which $\text{period}(\bar{g}_n^*)$ is computed.

Since $u^*$ is continuous in $A^e$, we have

$$u^*(p_n) \rightarrow u^*(P_0) \quad \text{as} \quad n \rightarrow \infty.$$  

(4.32)

By applying the analysis leading to the estimate in (4.20) with $p_n$ replacing $\omega_n$, we now conclude that (4.31) holds.

It now follows that (up to choosing a subsequence) the $\phi_n$’s converge uniformly on compact subsets of $A$ to

$$\Phi_A(z) = \exp \left( \frac{2\pi}{\text{period}(u^*)} (u(z) + i u^*(z)) \right).$$

(4.33)

We end the proof by recalling a classical result (see, for instance, [17, Section 7] or [60, Theorem 4.3]) which asserts that $\Phi_A$ is a conformal homeomorphism between the interiors of $A$ and $E_A$, respectively.
4.4 The case of continuous boundary

In this paragraph, we will briefly indicate why the boundary regularity assumption in Theorem 4.7 can be relaxed. Assume that $\mathcal{A}$ is a planar annulus, where $\partial \mathcal{A}$ is a union of disjoint, Jordan curves.

**Definition 4.9** ([42, I.6.7]) A sequence of planar annuli $\mathcal{R}_j \subset \mathcal{R}$, $j = 1, 2, \ldots$, with $\{C_{1j}, C_{2j}\}$ as the components of their complements, converges from the inside to an annulus $\mathcal{R}$ with $\{\mathcal{R}_1, \mathcal{R}_2\}$ as components of its complement, if the following holds: for every $\epsilon > 0$ there exists $n_\epsilon$ such that for $n \geq n_\epsilon$ every point of $(C_{ij})_{i=1,2}$ lies within a spherical distance less than $\epsilon$ of the set $(\mathcal{R}_i, \mathcal{R}_2)_{i=1,2}$.

A classical construction due to Kellogg [39, Chapter XI.14] grants us an existence of a nested sequence of annuli, $\{\mathcal{A}_i\}$, where for all $i > 0$, $\{\mathcal{A}_i\} \subseteq \mathcal{A}$, the boundary of $\mathcal{A}_i$ is polygonal, and the sequence converges to $\mathcal{A}$ from the inside. Furthermore, since each $\mathcal{A}_i$ is made of a lattice of squares, it is easy to construct a sequence of quasi-uniform triangulation of each $\mathcal{A}_i$, where each triangulation satisfies assumptions (V0)-(V3). Thus, $\mathcal{A}$ is presented as an increasing union of open subsets. The interiors of the $\mathcal{A}_i$ and each conformal embedding $\Phi_{\mathcal{A}_i}$ can be approximated according to Theorem 4.7. It follows that, up to normalization of the maps $\Phi_{\mathcal{A}_i}$, a subsequence of the $\{\Phi_{\mathcal{A}_i}\}$ will converge uniformly on compact subsets of $\mathcal{A}$, to its uniformizing map (see, for instance, [52, Lemma 2.2] or [10, Page 223]). Hence, we have the following

**Corollary 4.10** With the additional approximation processes described in the paragraph above, we may assume in Theorem 4.7 that $\partial \mathcal{A}$ is continuous.

The following figures depict the evolution of two polygonal annuli under the approximation scheme provided in Theorem 4.7 (Figs. 5, 6, 7).

![Fig. 5 Two triangulated polygonal annuli](image-url)
In this section, we will affirm Stephenson’s conjecture (Conjecture 1.1) which was originally stated for the case of a bounded, simply connected, planar domain. Our point of departure is Theorem 4.7 whose notation will be closely followed. The proof of this case entails on successively applying this theorem to an increasing sequence of annuli, a known modification of Koebe’s compactness theorem, Riemann’s removable singularity theorem, a lemma concerning the monotonicity of periods, and a basic covering property of planar Riemann surfaces.

In the following, we will let

$$\sigma(z) = \frac{1}{z},$$

(5.1)
be the standard inversion of \( \mathbb{C} \); it is well known that \( \sigma \) is conformal. We can now turn to

**Theorem 5.1** Let \( \Omega \) be a simply connected domain, embedded in \( \mathbb{C} \) and bounded by a closed, continuous curve \( \Gamma \); let \( p_0 \in \Omega \) be a fixed point. Let \( \{ \Omega_n \} \subset \Omega \) be a nested sequence of disjoint, polygonal, Jordan disks with polygonal boundaries \( \{ \Theta_n \} \) such that the disks converge to \( p_0 \), that is,

\[
\Omega_1 \supset \Omega_2 \supset \ldots \supset \Omega_k \ldots, \tag{5.2}
\]

\[
\text{mesh}(\Omega_n) \to 0 \text{ as } n \to \infty, \text{ and} \tag{5.3}
\]

\[
p_0 = \cap_n \Omega_n. \tag{5.4}
\]

For each \( n \), let \( \mathcal{A}_n = \mathcal{A}_n(\Omega, \Theta_n) \) be the polygonal annulus defined by \( \Omega \setminus \bar{\Omega}_n \) with \( \partial \mathcal{A}_n = \Gamma \cup \Theta_n \), endowed with a sequence of quasi-uniform triangulations \( \{ T_m, \mathcal{A}_n \}_{m=1}^{\infty} \), such that for all \( m = m(\mathcal{A}_n) \) large enough, \( T_m, \mathcal{A}_n \) satisfies the hypotheses of Theorem 4.7. Let

\[
\Phi_n = \Phi_n(\mathcal{A}_n) : \mathcal{A}_n \to \mathcal{E}_n \tag{5.5}
\]

be the sequence of conformal homeomorphisms constructed according to Eq. (4.9) onto the interior of concentric Euclidean annuli \( \mathcal{E}_n \), whose inner and outer radii are given by, respectively

\[
\{ R_1, R_2, \ldots \} = \left\{ 1, \exp \left( \frac{2\pi}{\text{period}(u_n^*)} \right) \right\}, \tag{5.6}
\]

where \( u_n^* \) is the (smooth) harmonic conjugate of \( u_n \), the solution of the boundary value problem (3.3) defined on \( \mathcal{A}_n \).

Then, a normalized subsequence of \( \{ \sigma \circ \Phi_n \} \) converges uniformly on compact subsets of \( \Omega \setminus p_0 \) to a holomorphic homeomorphism \( \Psi \) from \( \Omega \setminus p_0 \) onto \( \mathbb{D} \setminus 0 \). Furthermore, \( \Psi \) can be extended to be holomorphic over \( \Omega \).

**Proof** Following the rationale preceding Corollary 4.10, we may assume that \( \Gamma \) is polygonal. By construction, the \( \{ \mathcal{A}_n \} \) is a strictly increasing sequence, that is,

\[
\mathcal{A}_1 \subsetneq \mathcal{A}_2 \subsetneq \ldots \subsetneq \mathcal{A}_k \ldots \tag{5.7}
\]

which all share \( \Gamma = \partial \Omega \) as their outer boundary component, and with \( \Omega \setminus \{ p_0 \} \) being their union. The following lemma is needed in order to understand a monotonicity property of the sequence \( \{ \mathcal{A}_n \} \).

**Lemma 5.2** The sequence \( \{ \text{period}(u_n^*) \} \) is strictly decreasing.

**Proof** By Green’s theorem, for all \( n > 1 \) we have that,

\[
\int_{\mathcal{A}_n} |\nabla u_n|^2 \, dx + \int_{\mathcal{A}_n} \Delta u_n u_n \, dx = \int_{\partial \mathcal{A}_n} \frac{\partial u_n}{\partial n} \, ds. \tag{5.8}
\]
However, by the definition of period \( (u_n) \), and since \( u_n \) is the solution of the boundary value problem (3.3) defined on \( A_n \), for all \( n > 1 \), we have that

\[
\int_{A_n} |\nabla u_n|^2 \, dx = \text{period}(u_n).
\]  

(5.9)

It is clear that for all \( n > 1 \), \( u_n \) can be extended to be zero on \( A_{n+1} \setminus A_{n+1} \) to a piecewise smooth function on \( A_{n+1} \) having the same boundary values as those of \( u_{n+1} \). The assertion of the lemma now follows by the well-known characterization of \( u_{n+1} \) as the unique minimizer of the Dirichlet integral over \( A_{n+1} \).

**Lemma 5.2**

It follows from Eq. (5.1), Eq. (5.6) and the Lemma, that the sequence \( \{ A_n = \sigma(\mathcal{E}_n) \} \) consists of planar, concentric, Euclidean annuli, such that the inner and outer radii of each \( A_n \) are given by

\[
\{ r_1, r_{2,n} \} = \left\{ 1, 1/\exp\left( \frac{2\pi}{\text{period}(u_n)} \right) \right\},
\]  

(5.10)

respectively, where the sequence \( \{ r_{2,n} \} \) is strictly decreasing. Note that all the \( A_n \)'s share \( S^1 = \partial \mathbb{D} \) as their outer boundary component,

\[
A_1 \subsetneq A_2 \subsetneq \ldots \subsetneq A_k \ldots,
\]  

(5.11)

and the sequence \( \{ A_n \} \) exhausts \( \mathbb{D} \setminus \{0\} \) (Fig. 8).

Pick \( z_0 \in A_1 \), a local complex parameter at \( z_0 \), and a fixed \( \xi_0 \in \mathbb{C} \). For all \( n > 1 \), we now apply a normalization by post-composing \( \sigma \circ \Phi_n \) with a conformal embedding \( f_n : A_n \to \mathbb{C} \) so that the composed maps

\[
\Xi_n = f_n \circ \sigma \circ \Phi_n : A_n \to \mathbb{C}
\]  

(5.12)

satisfy

\[
\Xi_n(z_0) = \xi_0 \text{ and } \Xi'_n(z_0) = 1.
\]  

(5.13)

Note that the image of each \( A_n \) is still a concentric Euclidean annulus, yet the sequence \( \{ \Xi_n(A_n) \} \) is not (generically) concentric. Nevertheless, it follows from a modification of Koebe’s compactness theorem (see, for instance, [16, Proposition 7.15]) and a Cantor diagonalization process, that a subsequence of the \( \{ \Xi_n \} \) converges uniformly on compact subsets of \( \Omega \setminus p_0 \), to a conformal, univalent mapping

\[
\Xi : \Omega \setminus p_0 \to \mathbb{C},
\]  

(5.14)

which is obviously not constant. It is also evident that \( \Xi \) is bounded, and therefore, by Riemann’s removable singularity mapping theorem, can be extended to a conformal, univalent, embedding from \( \Omega \). Hence, the extended map must be equal to the Riemann mapping with the same normalization. This ends the proof of the Theorem.
Our current research is addressing the following themes.

1. **Disk packing and quasi-uniform triangulations.** It is well known (see, for instance, [19, Section 5]) that a sequence of disk packings satisfying some minor conditions, induce (as explained in A.4) a sequence of quasi-uniform triangulations, that will in addition satisfy assumptions (V0) and (V1). However, assumption (V2) (see page 14) will not always be satisfied; it will be satisfied (for instance) for sub-packings of scaled copies of the infinite hexagonal disk packing (which were the subject of Thurston’s original conjecture). Recall that assumption (V2) is used in the proof of Theorem 4.7 only in the part addressing the convergence of the $\bar{g}_n^*$.

2. **The case of higher connectivity.** As mentioned in introduction, Stephenson’s original conjecture can be formulated for any finitely connected, Jordan domain. However, several issues need to be addressed before an appropriate statement can be made. For instance, the existence of singular points and level curves for smooth harmonic functions solving a Dirichlet problem (analogous to the one in Theorem 4.7) on such domains needs to be addressed.

3. **Effective computational approach through parallel processing.** Polygon approximation of the boundary curves in the 2D or the 3D shape is essential for the
computational aspects of this work and its successors. It will be used to smooth out any irregularities which may be present in the planar curves due to various effects and to achieve data reduction. In order to turn the computational problem to a parallel processing scheme, it is natural to utilize techniques from [4,38] and a decomposition of the given domain to subdomains as proposed in [34]. Finally, we will compare our computational results with those obtained in [5] for the cases of scaling and rotation which are two useful transformations in the field of computer vision and imaging.

Acknowledgements We are indebted to Gilles Courtois for carefully reading this paper, a great deal of help in clarifying several proofs and in making the presentation lucid. Ridgway Scott, Thierry Gallouet, and Al Schwatz are heartily thanked for graciously sharing with the author their insights regarding the subtle analysis involved in numerical methods for convex and non-convex planar domains. We are grateful to Benson Farb, Rich Schwartz, Ted Shifrin, and Robert Varley for their patient listening, and valuable discussions during the preparation of this paper. Our gratitude to Eric Perkerson for essential help in implementing the algorithm in Theorem 4.7 (see, for instance, the illustrations on page 22).

Appendix A: Preparatory facts

A.1. The finite element method

In this section, we will assume that \( \Omega \) is a fixed, bounded, \( m \)-connected with \( m \geq 2 \), polygonal domain in \( \mathbb{R}^2 \). The finite element method (FEM) is a powerful discretization scheme, aimed at constructing and presenting approximations of solutions of partial differential equations in the form of algebraic set of equations; the unknowns are the coefficients of a linear combination of the basis elements of a linear space comprising of simple functions: piecewise linear polynomials.

The phrase “finite element” reflects on the process of approximation. The domain in which the boundary value problem is define is divided into a collection of subdomains, where each subdomain is presented by a set of element equations derived from the original problem. One then systematically combines all of the sets of element equations into a global system of equations for the final calculation.

We now turn to a specific boundary value problem that we will consider, the homogeneous Dirichlet equation: Given \( f \neq 0 \in L^2(\Omega) \), find \( \tilde{u} \in C^2(\Omega) \cap C(\bar{\Omega}) \) satisfying

\[
\triangle \tilde{u} = f \text{ in } \Omega, \quad \text{and } \tilde{u} = 0 \text{ on } \partial \Omega.
\]  

(A.1)

Such a solution is called a strong solution.

A common theme in finite element method is to triangulate the domain in a geometric convenient way.

Definition A.1 A triangulation \( \mathcal{T} \) of \( \Omega \) is a set of (closed) triangles \( T_i, i = 1, \ldots, n \) such that the following hold

\[
\bar{\Omega} = \bigcup_{i=1}^{n} T_i, \text{ and } T_i \cap T_j = \emptyset, \text{ a vertex or one common edge, for all } i \neq j. \]  

(A.2)

The following quantity is associated with a fixed triangulation.
Definition A.2 Let $T$ be a triangulation on $\Omega$, the mesh size of $T$ is equal to

$$\sup_{T \in T} d(T),$$

(A.3)

where $d(T)$ denotes the diameter of $T$ (i.e., the length of its largest edge). Henceforth, $T_\rho$ will denote a triangulation of $\Omega$ of mesh size that is equal to $\rho$.

In order to apply the machinery of numerical approximation of elliptic boundary value problems, one needs to avoid situations where triangles, in any triangulation $T_\rho$ of the domain, become flat as $\rho \to 0$. To this end, we let $\sigma(T)$ denote the diameter of the largest circle that can be inscribed in a triangle $T$. We now define the geometric property of the special class of triangulations that will be used throughout this paper.

Definition A.3 A family of triangulations $\{T_\rho\}$ of $\Omega$ is called $\tau$-quasi-uniform (or $\tau$-quasi-regular) when $\rho \to 0$, if there exists a positive constant $\tau$ such that

$$\frac{d(T)}{\sigma(T)} \leq \tau \text{ for all } T \in T_\rho, \text{ and for all } \rho \text{ small enough.}$$

(A.4)

Given a triangulation we will now associate to it a vector space of functions.

Definition A.4

$$\mathbb{V}_{0,T} = \{ \phi : \Omega \to \mathbb{R} | \phi \in C(\bar{\Omega}), \ v|T \in P_1(T) \text{ for all } T \in T \text{ and } \phi = 0 \text{ on } \partial \Omega \},$$

(A.5)

where $P_1(T)$ denotes the space of linear polynomials in two variables over $T$.

Let $V^0(T)$ denote the set of vertices in $T^{(0)}$ which are in the interior of $\Omega$, and set

$$M_1 = |V^0(T)|, \ M_2 = |T^{(0)} \cap \partial \Omega| \text{ and } M = M_1 + M_2 (= |T^{(0)}|).$$

(A.6)

It is well known that $\mathbb{V}_{0,T}$ is a finite-dimensional vector space which is spanned by $\{\phi_i\}$ - the nodal basis, where by definition

$$\phi_i(x_j) = \delta_{i,j}, \text{ for all } x_j \in V^0(T), i = 1, \ldots, M_1.$$  

(A.7)

One important feature of $\mathbb{V}_{0,T}$ is that it is a linear subspace of a certain Sobolev space. Let us first recall

Definition A.5 The Sobolev space $H^{1,2}(\Omega)$ is the subset of $L^2(\Omega)$ defined by

$$H^{1,2}(\Omega) = \{ v \in L^2(\Omega) | \partial_x v, \partial_y v \in L^2(\Omega) \},$$

(A.8)

where $\partial_x v, \partial_y v$ denote the distributional derivatives of $v$ in the $x$ and the $y$ directions, respectively. The integration is with respect to the standard Lebesgue measure in the plane which will be denoted by $dx$. 

\(\text{ Springer}\)
For \( u, v \in H^{1,2}(\Omega) \), one defines the scalar product and an associated norm, respectively, by
\[
(u, v)_{1,2} = \int_{\Omega} (uv + \nabla u \cdot \nabla v), \quad |u|_{1,2}^2 = (u, u)_{1,2}
\] (A.9)
where \( \nabla v = (\partial_x v, \partial_y v) \), and the scalar product is the Euclidean one in \( \mathbb{R}^2 \). It is well known that \( H^{1,2}(\Omega) \) equipped with this scalar product is a Hilbert space. Finally, let \( H_0^{1,2}(\Omega) \) be defined as the closure of \( C_0^\infty(\Omega) \) in \( H^{1,2}(\Omega) \) with respect to this norm. Equipped with this scalar product \( H_0^{1,2}(\Omega) \) is a Hilbert space as well. It is a useful fact that \( \mathbb{V}_{0,\mathcal{T}} \) is a linear subspace of \( H_0^{1,2}(\Omega) \).

The first step in finite element method amounts to finding the weak solution of the boundary value problem (A.1). That is, finding \( u \in H_0^{1,2}(\Omega) \) such that
\[
\int_{\Omega} \nabla u \cdot \nabla v \, dx = \int_{\Omega} f v \, dx, \quad \text{for all } v \in H_0^{1,2}(\Omega).
\] (A.10)

Next, one replaces the space \( H_0^{1,2}(\Omega) \) by a sequence of linear subspaces that exhaust it, i.e., one lets \( \rho \) converge to zero and search for a solution of the above equation in \( \mathbb{V}_{0,\mathcal{T}_\rho} \): Finding \( u_\rho \in \mathbb{V}_{0,\mathcal{T}_\rho} \) such that
\[
\int_{\Omega} \nabla u_\rho \cdot \nabla v_\rho \, dx = \int_{\Omega} f v_\rho \, dx, \quad \text{for all } v_\rho \in \mathbb{V}_{0,\mathcal{T}_\rho}.
\] (A.11)

In Sect. 4.2, we recall a foundational result concerning the convergence of the piecewise linear polynomials \( u_\rho \) as \( \rho \) converges to zero.

### A.2. Stephenson’s conductance constants—a finite element method perspective

In this section, we will work with an explicit form of the solution \( u_\rho \) of (A.11). We will recall the known fact that \( u_\rho \) (for each \( \rho \)) can be derived from the solution of a system of finitely many linear equations. Following this, we will define a quantity, the discrete flux of \( u_\rho \), which will be used in this paper to approximate the analytical flux of \( u \), the solution of (A.1). To this end, note that the interpolation conditions in (A.7) allow us to write in a unique way
\[
u \rho(x) = \sum_{i=1}^{M_1} u_\rho(x_i) \phi_i(x), \quad \text{for } x \in \Omega,
\] (A.12)
where the unknowns are \( u_\rho(x_i) \) for all \( i = 1, \ldots, M_1 \). Therefore, if we define \( u_\rho(i) = u_\rho(x_i) \) for all \( i = 1, \ldots, M_1 \), then our vector of unknowns for \( u_\rho \) is given by \( u_\rho = (u_\rho(1), \ldots, u_\rho(M_1)) \). Hence, (A.11) can be written as the following matrix equation
\[
A_\rho \xi_\rho = q_\rho,
\] (A.13)
where we have for all $i, j = 1, \ldots, M$

\[
(A_{\omega})_{i,j} = \int_{\Omega} \nabla \phi_j \cdot \nabla \phi_i \quad \text{(A.14)}
\]

\[
(q_{\omega})_i = \int_{\Omega} f \phi_i
\]

We keep the notation as in the discussion preceding Fig. 2. The following lemma and its corollary allow us to turn each $T_\rho$ into a finite network and provide a relation between Stephenson’s constants and the finite element method.

**Lemma A.6** ([3, Lemma 6.8]) Let $T$ be any fixed triangulation of $\Omega$, and consider its corresponding Voronoi diagram. Then, for an arbitrary triangle $T \in T_\rho$ with vertices $x_i, x_j (i \neq j)$, the following relation holds

\[
\int_T \nabla \phi_j \cdot \nabla \phi_i \, dx = -\frac{m^T_{(i,j)}}{d_{ij}}, \quad \text{(A.15)}
\]

where $m^T_{(i,j)}$ is the length of the segment of $\Gamma_{ij}$ which intersects $T$.

A computation then shows that

**Corollary A.7** [3, Corollary 6.9] Under the assumptions of Lemma A.6, we have

\[
\int_\Omega \nabla u_\rho \cdot \nabla \phi_i \, dx = \sum_{x_j \sim x_i, j \neq i} \frac{m_{(i,j)}}{d_{ij}} (u_\rho(x_i) - u_\rho(x_j)). \quad \text{(A.16)}
\]

Hence, by letting the index $i$ range over the indices of the interior vertices (i.e, those that are in $V^0_\rho (T_\rho)$), (A.14) turns into the following system of linear equations

\[
\sum_{x_j \sim x_i, j \neq i} \frac{m_{(i,j)}}{d_{ij}} (u_\rho(x_i) - u_\rho(x_j)) = \int_\Omega f \phi_i \, dx, \text{ for all } i = 1, \ldots, M. \quad \text{(A.17)}
\]

**Remark A.8** Note that when $f \equiv 0$, $u_\rho$ is a discrete harmonic function on $T_\rho^{(0)}$ with the conductance constant $\frac{m_{(i,j)}}{d_{ij}}$ for the edge joining $x_i$ to $x_j$.
