ABSTRACT—The dodo *Raphus cucullatus* Linnaeus, 1758, an extinct and flightless, giant pigeon endemic to Mauritius, has fascinated people since its discovery, yet has remained surprisingly poorly known. Until the mid-19th century, almost all that was known about the dodo was based on illustrations and written accounts by 17th century mariners, often of questionable accuracy. Furthermore, only a few fragmentary remains of dodos collected prior to the bird’s extinction exist. Our understanding of the dodo’s anatomy was substantially enhanced by the discovery in 1865 of subfossil bones in a marsh called the Mare aux Songes, situated in southeastern Mauritius. However, no consistent information was recorded during early excavation efforts, and the majority of excavated material comprised larger dodo bones which were unassociated. Here we present a modern interdisciplinary analysis of the Mare aux Songes, a 4200-year-old multitaxic vertebrate concentration Lagerstätte. Our analysis of the deposits at this site provides the first detailed overview of the ecosystem inhabited by the dodo. The interplay of climatic and geological conditions led to the exceptional preservation of the animal and associated plant remains at the Mare aux Songes and provides a window into the past ecosystem of Mauritius. This interdisciplinary research approach provides an ecological framework for the dodo, complementing insights on its anatomy derived from the only associated dodo skeletons known, both of which were collected by Etienne Thirioux and are the primary subject of this memoir.

Rijsdijk (eds.), Anatomy of the Dodo (*Raphus cucullatus* L., 1758): An Osteological Study of the Thirioux Specimens. Society of Vertebrate Paleontology Memoir 15. Journal of Vertebrate Paleontology 35(6, Supplement).

INTRODUCTION

The dodo *Raphus cucullatus* Linnaeus, 1758 (Fig. 1), a giant, flightless pigeon endemic to the Mascarene island of Mauritius, became extinct just three centuries ago—a blink of an eye in terms of geological time—yet the historical record prior to the discovery of subfossil skeletal material of this vanished species comprises just a few scraps of skin, a small number of bones, and a handful of inadequate pictures and accounts (see Hume, 2006; Parish, 2013). Strickland and Melville (1848:5–6) presented a most fitting summary in their now classic monograph on the dodo, highlighting the complications that study of a species so recently lost to the world could entail:

> In the case of the *Didiniae*, it is unfortunately no easy matter to collect satisfactory information as to their structure, habits, and affinities. We possess only the rude descriptions of unscientific voyagers, three or four oil paintings, and a few scattered osseous fragments, which have survived the neglect of two hundred years. The palaeontologist has, in many cases, far better data for determining the zoological characters of a species which perished myriads of years ago, than those presented by a group of birds, several species of which were living in the reign of Charles the First.

This monograph, the third of its kind, complements two earlier monographic works on the subject, those of Strickland and Melville (1848) mentioned above and Owen (1866a). All previous osteological work was based upon unassociated, composite skeletons, combining bones from many individuals and both sexes. Therefore, precise reconstructions based on associated skeletal elements of the dodo’s physique, locomotion, and physiology were not possible (Hume, 2005; Meijer et al., 2012; Hume et al., 2014a; Claessens et al., 2015a). In this memoir (Claessens et al., 2015b), we describe the osteology of two nearly complete, associated skeletons of the dodo that were collected around 1900 by French-born amateur naturalist Louis Etienne Thirioux in caves or, more likely, boulder scree in the valleys surrounding the mountains of central Mauritius (Hume, 2005; Claessens and Hume, 2015). These skeletons are presently housed at the Mauritius Institute in Port Louis and at the Natural Science Museum in Durban, South Africa, but have not been studied in detail previously.

The bulk of the dodo subfossil material for pre-2005 studies on dodo anatomy were retrieved from an exceptionally rich vertebrate concentration Lagerstätte preserving multiple taxa called the Mare aux Songes, a marsh situated in a rocky valley near the southeastern coast of Mauritius (Fig. 2A; Rijsdijk et al., 2009; Hume et al., 2014a). The 1.8-ha Lagerstätte situated in sub-basin I, the major sub-basin of the valley complex (Figs. 2B, C), comprises an up to 0.5 m thick bonebed containing more than 20 vertebrate species, plant remains, terrestrial and freshwater mollusk and insect subfossils, and a suite of microfossils. Remarkably, the vertebrate subfossils in sub-basin I accumulated in less than a century ca. 4200 years ago, suggesting mass mortality events led to its formation (Fig. 2D; Rijsdijk et al., 2009). Paleoecological research has shown that the vertebrate mass mortality was triggered by a series of extreme climatic drought events that affected a large part of the southwestern Indian Ocean region (De Boer et al., 2014, 2015). A unique combination of local geomorphic and hydrotaphonomic factors, coupled with eustatic sea level rise, resulted in excellent preservation of the subfossil material, which provided data for interdisciplinary research on the taphonomy and ecology of the Mare aux Songes bonebed (Hume, 2005; Rijsdijk et al., 2009, 2011; Meijer et al., 2012; Hume et al., 2014a).

This bonebed has produced evidence enabling a high-resolution study of the ecosystem of the dodo, whereas our new analysis of the Thirioux dodo skeletons allows for the first osteological studies of associated remains of single individuals (see Claessens et al., 2015a). We further discuss the excavation history of the Mare aux Songes bonebed since its discovery in 1865, the subsequent work from 2005 to 2011, and explain how the bonebed was formed and how it was modified by environmental processes. We present clarification of how this insular ecosystem functioned under changing environmental conditions. Finally, we reflect on the environmental and human-induced stresses that the dodo and contemporary species must have endured on the island of Mauritius and what we can learn from the dodo on the potential resilience of insular vertebrates.

HISTORICAL BACKGROUND

The isolated Mascarene Islands, comprising Mauritius, Reunion, and Rodrigues, are volcanic in origin and situated in the southwestern Indian Ocean. Mauritius lies 829 km east of Madagascar, the nearest large landmass (Fig. 2A). Arab traders probably discovered the Mascarene Islands as early as the 13th century (Hume, 2013), followed by the Portuguese in the early 16th century, but neither the Arabs nor Portuguese settled there,
As more information became available from returning mariners, the publications were expanded, and the first published depiction of the dodo appeared in 1600, followed by a second edition in 1601 (Fig. 3A; Anonymous, 1601). The importance of Mauritius as a ship refurbishment station was soon realized, and the island became an important stopover for outward and homeward bound VOC fleets. With the increase of European competitors in the Indian Ocean, the VOC established a permanent settlement in 1638, constructing Fort Frederik Hendrik beside the southeastern harbor, the present-day Vieux Grand Port (Fig. 2A). This period of occupation, which saw the introduction of slaves from Madagascar and cutting down of ebony trees, ended in 1658, when the VOC abandoned the island. In 1652, the Cape of Good Hope was developed as an excellent port of call, which left Mauritius as a costly and superfluous establishment (Sleigh, 1993). However, with continued threats from rival English and French trading fleets, the Dutch reestablished a settlement on Mauritius in 1664, before abandoning the island completely in 1710 (Moree, 1998). During the second period of Dutch occupation, the population grew to 251, consisting of a few VOC servants, mostly farmers (freeburghers, some of them second generation) and slaves. The establishment managed to overcome the initial hardships of survival and depended more or less successfully on husbandry (Sleigh, 1993, 2000), while the felling of ebony trees and clearing for cattle farming was reestablished. The introduced invasive species must have had a great impact on the island’s ecosystems, ultimately resulting in the extinction of the dodo and several other endemic species (Floore and Schrire, 1997; Griffiths and Flores, 2006; Cheke and Hume, 2008; Peters et al., 2009; Floore and Jayasena, 2010). During this period, live dodos and other Mauritian birds were shipped to Europe, India, and Japan (Cheke and Hume, 2008; Winters and Hume, 2014; Hume and Winters, 2015).

The first faunal and floral studies of Mauritius were made during the French occupation (1715–1810), long after the dodo had disappeared; therefore, our understanding of the bird and its ecology was largely restricted to 17th century mariners’ accounts and illustrations. Very few specimens arrived in European museum collections, and most of those succumbed to insect damage (Hume, 2006). Such was the paucity of physical evidence that the very existence of the dodo was doubted by some scientists (Hume, 2006); however, John Duncan, curator at the Ashmolean Museum, described a desiccated dodo head (Fig. 1) and foot held at the museum (Duncan, 1828). John Theodore Reinhardt, a Danish professor, examined a second dodo skull at the Copenhagen Museum and concluded that it was a giant pigeon (Reinhardt, 1842). This notion was initially met with ridicule until the monograph of Strickland and Melville (1848) was published, which confirmed the dodo’s columbid affinities. Strickland and Melville had the skin of the Oxford skull and foot dissected in order to study the cranium and tarsometatarsus (Hume et al., 2006), and they also figured a desiccated foot once held at the then British Museum (Natural History) (now the Natural History Museum, London).

Further interest in the dodo was created after the publication of Charles Darwin’s ‘Origin of Species’ in 1859. Alfred Newton, a natural historian based at the University Museum of Zoology, Cambridge, U.K., was especially interested in the dodo and had just applied to become first professor of comparative anatomy and zoology at the university (Hume et al., 2009). Newton regularly corresponded with Darwin and became one of the first disciples of Darwin’s theory (Hume et al., 2014b). Alfred’s brother Edward, who was assistant Colonial Secretary on Mauritius, also had a great interest in natural history and was ideally located to report the discovery of any dodo fossil material (Hume et al., 2009, 2014b). Richard Owen, superintendent at the British Museum (Natural History), who became a stern adversary of...
FIGURE 2. A, location of Mauritius in the southwestern Indian Ocean and locations of Mare aux Songes (MAS), Fort Frederik Hendrik (FFH), and Lake Tatos (MTS); B, map of Mare aux Songes and the sub-basins near the coast. Rectangular frame shows extent of inset C; C, geomorphological map of the Mare aux Songes area showing positions of all sub-basins (0, I, II, III) and locations of trenches TR1 (TR0), TR2, and TR3 (TR4). Rectangular frame shows extent of inset D; D, left panel showing extent of marsh at sub-basin I. The dashed line represents the longitudinal cross-section with positions of dated and undated samples from cores, scoops, and trenches. Right panel showing the longitudinal cross-section through the marsh with locations of radiocarbon dated samples (see Table 1). B is carbonate sands, C is lake marl and gyttja, D is fossil layer, and E is dumped basalt boulder layer.
Darwin’s theory, was also keen to receive dodo fossil material. He made a request to the Bishop of Mauritius, Vincent Ryan, to notify him should any dodo remains be found. Owen had also written a testimonial in favor of Alfred’s request to become professor and hinted that his support carried more weight than any other (Hume et al., 2009).

Around the same time, Charles Dodgson (better known by his pen name, Lewis Carroll) included the dodo in his best-selling novel ‘Alice’s Adventures in Wonderland,’ published in 1865 (Fig. 3B). The dodo was immortalized in the book by the illustrator John Tenniel, who based his image on an iconic painting of a dodo by a Flemish artist, Roelandt Savery (Fuller, 2002) (Fig. 3C). The book became an international bestseller and was available across the entire British Empire, adding to the fame of the dodo.

The publication of ‘Alice’s Adventures in Wonderland’ coincided with a spectacular discovery of subfossil dodo bones at Mare aux Songes in Mauritius in 1865 (Clark, 1866; Hume et al., 2009). Harry Higginson, a railway engineer, chanced upon the site when imported laborers were digging for peat and stockpiling bones and informed a local schoolteacher and amateur natural historian, George Clark (see Hume et al., 2009; Hume, 2012). Clark monopolized the site and sent a first consignment of bones to Richard Owen in September 1865. However, under instruction from Edward Newton, Clark organized another shipment of bones for Alfred, who was intending to sell them by auction the following year. Owen was tipped-off about the consignment by Captain Mylius, Clark’s brother-in-law, and Owen intercepted the bones. He arranged a new deal with Clark via Mylius and promptly retained all of the material. Alfred was obviously furious, which in part may have been because of the loss of financial gain, and was going to make a formal complaint, but Owen blatantly blackmailed Alfred from taking any further action by threatening his application to become professor at Cambridge.

Alfred had to relinquish his claim on the dodo and also had to withdraw a manuscript describing the dodo’s anatomy. Owen wasted no time in monopolizing the discovery, giving public lectures in January 1866, before publishing his first monograph on the dodo in October of that year (Owen, 1866a; Hume et al., 2009). Crucially, this monograph and Owen’s reconstructed skeleton were based on unassociated dodo bones from dozens of individuals of unknown age and sex, which were retrieved from the small (0.33 ha) sub-basin 0 situated adjacent to sub-basin I of the Mare aux Songes (Hume et al., 2014a; Fig. 2C). Regardless, this work served as a key reference on the morphology, physiology, and biology of the dodo for subsequent workers over the next 150 years (Livezey, 1993; Cheke and Hume, 2008; Hume et al., 2014a).

Such was the interest in the dodo in 1865 that virtually all other subfossil material was ignored; only one new species of parrot, Lophopsittacus mauritianus, was described from the Mare aux Songes based on a single mandible (Owen, 1866b), a specimen that was inadvertently included amongst the dodo remains sent to Owen. The following year, the French comparative anatomist, Alphonse Milne-Edwards, received rallid specimens from the Mare aux Songes from Edward Newton (Milne-Edwards, 1867), from which he described a new coot, Fulica newtonii Milne-Edwards, 1867. Albert Günther, a reptile specialist at the British Museum (Natural History), received some giant tortoise remains in the early 1870s from which he described two species (see Günther, 1877). The Mare aux Songes was reexplored in 1889 under the guidance of Théodore Sauzier, when six new species of bird were described from subfossil bones (Newton and Gadow, 1893).

The family of the amateur naturalist Paul Carié inherited the Mare aux Songes site in 1902 (Hume et al., 2009), so Carié was able to collect more material. He obtained further dodo bones and new species of reptile, all of which were deposited at the
Muséum National d’Histoire Naturelle (MNHN), Paris (Hume, 2012). The last excavations of sub-basin 0 took place in the 1930s, but no previous work included detailed contextual descriptions of the faunal and floral diversity and the geological context of the site (Hume et al., 2014a). The infilling of the sub-basins of the Mare aux Songes in 1943 to combat malaria prevented any further excavations, after which the site was largely forgotten (Van Wissen, 1995).

THE REDICOVERY OF MARE AUX SONGES

The rediscovery of the Mare aux Songes fossil site in 2005 was partly due to an investigation by a University of Tokyo research team in 1995, in collaboration with the owners of the then Mon Trésor, Mon Desert (MTMD) Sugar Estate (now Omnicane) and Mauritius Sugar Industry Research Institute (MSIRI). The Japanese team used coring equipment to penetrate the dumped boulder layer capping sub-basin I, in search of the bonebed discovered by Clark in 1865 (Grihault, 2005; Fig. 2C) and were successful in finding bone fragments, including dodo. However, due to a series of unfortunate events, when both of the principal organizers of the excavations died within a short time of each other (see Hume et al., 2014a), the results were not scientifically published; again the site remained neglected.

In 2005, K.F.R. and F.B. were invited to Mauritius by archaeologist P.F., project leader of the archaeological excavations at Fort Frederik Hendriks at Vieux Grand Port, to reconstruct the landscape as it was prior to human settlement, based on Quaternary geological and palynological reconstructions (Floore and Schrire, 1997; Floore and Jayasena, 2010; Fig. 2A). The primary aim of the archaeological project, which began in 1997, was to locate the first human settlement on Mauritius and compare findings with documentary records. The fort’s archaeological record proved extremely productive and not only provided 17th century
information on the building structures and human population, but also revealed the nature and impact of the human colonization (Peters et al., 2009). During archaeological excavations at Fort Frederik Hendrik from 1995 until 2006, 10,000 bones were found of animals slaughtered during the Dutch occupation from 1638 to 1710 (P. Floore, pers. comm., 2006; Peters et al., 2009). The remains of native animals included dugong Dugong dugon (Statius Müller, 1776), some birds, and giant tortoises, but dolphins were absent (Floore and Jayasena, 2010). The anthropogenic deposits of Fort Frederik Hendrik, consisting of clayey soils, proved unsuitable for the conservation of pollen needed for the environmental reconstruction of the 17th century habitation. In consequence, a program was set up in 2005 to identify marsh and peat deposits in an area of approximately 10 km around the excavation site to provide a palynological context. One of these selected spots was the Mare aux Songes (Nauta, 2006).

To collect pollen samples from the Mare aux Songes for palynological studies, it was attempted in 2005 to penetrate the duned boulders at the marsh, but without success. In turn, MTMD offered the above-mentioned cores for description, and these were instrumental in obtaining permission to reexcavate the Mare aux Songes by means of a mechanical digger. Trench TR0 excavated in sub-basin I proved extremely rich in bone and plant remains and led to the rediscovery of the vertebrate concentration Lagerstätte (Nicholls, 2005; Rijsdijk et al., 2009; Fig. 2B). The bone material, comprising bird, mammal, reptile, and fish, was set in a matrix of peat, intermixed with subfossil wood stems, leaves, macroscopic seeds and fungi, along with insect and terrestrial and freshwater mollusk remains. Most importantly, the richness of the Mare aux Songes subfossil locality gave an unprecedented insight into the paleoecology of Mauritius, long before the island was discovered by humans. As a result of the discoveries, the Dodo Research Programme was initiated, in order to address the following questions: (1) How did the Lagerstätte form? (2) How did the vertebrates accumulate at the site, and (3) What can we learn from the Lagerstätte about the ecology and biology of the biota of Mauritius before human arrival? The methods to answer these questions effectively followed those outlined by Behrensmeier and Kidwell (1985).

The site was excavated for six successive years. In the first year (Expedition I), the aim was to assess the fossil richness of the sub-basins. A succession of 10 exploratory cores were taken, which established that only sub-basins I and III contained vertebrate remains (Fig. 2C). Basin 0 was sampled to establish the location remained unknown at that time (Hume et al., 2014a). In addition, piezometers (pressure sensors) were installed in each of the three sub-basins, at 1 and 3 m below surface levels, to monitor the groundwater table and to analyze water samples (Rijsdijk et al., 2009, 2011). Mechanical digging machines excaved three trenches (TR): TR1 at the margin of basin I, TR2 in sub-basin III, and TR3 in the middle of sub-basin I (Fig. 2C). Bulk samples were sieved from all trenches (Rijsdijk et al., 2009). The first excavation was also crucial in establishing a methodology for undertaking a scientific excavation below the water table (Hume et al., 2014a).

The subsequent expeditions focused on excavating in situ by creating a dry trench (TR4) in sub-basin I, close to TR3. TR4 was so rich in vertebrate bones that it took two expeditions (Expedition II: 2007, Expedition III: 2008) to process the bone material, with more than 100 × 100-liter sacks being used for the excavated sediment. It took another four sessions (Expeditions IV–VI; 2009–2011) to finish the in situ excavations in TR4, which included the recording of three-dimensional (3D) orientations of individual bones (Rijsdijk et al., unpubl. data). A total of 27 samples were taken for radiocarbon dating (Table 1; Fig. 2D). The Mare aux Songs fossil locality is now completely protected within a fenced boundary at Omnicane, and members of the Dodo Research Programme are still processing the finds.

THE SETTING OF MARE AUX SONGES

Mare aux Songs is a rocky valley formed <100 ky ago, possibly as a combination of lava tunnel collapse and phreato-magmatic explosive activity (De Boer et al., 2105). The valley comprises four sub-basins, three of which, sub-basins 0, I, and III, contain subfossil bones (Fig. 2B). The mean groundwater level is approximately 0.5 m below present land surface level. The basins are hydrologically connected with the ocean through permeable basalts (Fig. 4), and as a result, fresh groundwater overlies a saline water wedge that increases in thickness towards the ocean, less than 2 km away. As a consequence, the groundwater levels fluctuate in phase with the tide, resulting in the saline groundwater wedge increasing the salinity of the water in the sub-basins. Present water salinity increases from sub-basins I to III, from low- (90 mS/m) to high- (580 mS/m) brackish conditions, respectively (Rijsdijk et al., 2009). The freshwater input at Mare aux Songs is through upwelling groundwater that is mainly derived from net rainfall from the Mauritius uplands. The precipitation at Mauritius is influenced by the Southern Hemisphere monsoon system, and the precipitation is highest from November to April. The coastal lowlands (<50 m elevation) under influence of dry cool easterly trade winds experience a dry season from May to October (Senapathi et al., 2010). Mean annual precipitation varies with altitude, with mean annual rainfall of more than 4000 mm in the Mauritius uplands (>300 m) and less than 1300 mm in the eastern coastal lowlands where the Mare aux Songs is situated. In this region, mean annual evapotranspiration exceeds mean annual precipitation, resulting in water deficit most of the year (Padya, 1989). Two years of continuous measurements of groundwater fluctuations indicate that the water tables are sensitive to the balance of net rainfall and evaporation within the Mare aux Songs catchment area (Fig. 4A, B). Furthermore, groundwater tables vary with the seasons: during the wet season water tables are ca. 300 mm higher and during the dry season 200 mm lower than the mean groundwater level (Rijsdijk et al., 2011).

STRATIGRAPHY

Sedimentological analyses of five mechanical digger scoop samples and seven cores in sub-basin I (Fig. 1) demonstrated that the bonebed (unit D in Fig. 5A) at the Mare aux Songs is a continuous lenticular bed, spanning 1.8 ha, that is 0.4 m thick at its margins and achieves its greatest thickness (ca. 0.75 m) in the center of the marsh (Rijsdijk et al., 2009, 2011). However, the continuity of the bonebed is disrupted by basaltic rocks (unit E) that were dumped in 1943 and have sunk into the peaty bonebed (unit D) (Fig. 5A; Rijsdijk et al., 2009, 2011; De Boer et al., 2015). In the center of the marsh, at the base of the peaty bonebed, the peat is rich in wood stems and rootlets. The bonebed is underlain by a basal gyttja–lake marl bed (unit C). Both gyttja and lake marl are organic sediments formed by degraded remains of plants and microscopic animals in a lake setting, whereby marl is particularly rich in calcium-carbonate due to the upwelling carbonate-rich groundwater. Both the bonebed (unit D) and the gyttja–lake marl beds (unit C) thin at the margins of the paleolake (TR0, TR1), where they are up to 0.4 and 0.2 m thick, respectively, but both units thicken towards the center of the paleolake (TR3, TR4), where they become up to 0.75 and 1.15 m thick, respectively (De Boer et al., 2015). Near the edges of the paleolake the bonebed forms a wood- and bone-supported mass (Fig. 5B). Even the matrix of this bone mass comprises smaller bone fragments (<5 mm), mixed with plant debris and peat (Rijsdijk et al., 2009, 2011). Towards the center of the sub-basin, as the bonebed (unit D) and underlying organic beds (unit C) increase in thickness, a corresponding
increase in peat matrix leads to the bonebed being matrix-supported. In this region, bones form local clusters or are dispersed in the peat matrix (Fig. 5C). Here the peaty bonebed grades upwards into a ca. 30 cm thick, horizontally laminated, dense peat layer interstratified with a distinct ca. 5 cm thick seed layer. The dark-brown peat forming the matrix of the bonebed comprises a compacted mass of nonsticky, decomposed plant debris rich in small seeds (<1 mm). The presence of one or two discontinuous laminae of coral sand within the bonebed reflects a subaerial influx of coral sands in sub-basin I from the nearby beach sands, likely blown into the sub-basin during cyclones.

Hydrological data, diatoms, and pollen provide evidence of frequent lake margin floor exposures during the drought events 4200 years ago, which, in turn, explains the coarseness of the
matrix of the bonebed at the former lake edge (Rijsdijk et al., 2009, 2011). The decomposed peaty materials were washed out by wind and wave action at the lake shore, resulting in a concentrated bonebed. In contrast, tranquil conditions occurred in the deeper parts of the lake, which accounted for an accumulation of finer organic peat debris (<1 mm), leading to a thicker matrix-supported bonebed with bones locally dispersed in peat. The basal woody peat bed forming the base of the bonebed (unit D) is up to 30 cm thick and contains various tree stems and branches that lie at a low angle relative to the former lake floor. These floral remains, which include rootlets and stems (Vernimmen et al., unpubl. data, see below), represent a classic sea-level-driven drowning of terrestrial arboreal vegetation when the lake deepened during Holocene sea level rises ca. 5000 years ago (Rijsdijk et al., 2011; De Boer et al., 2014, 2015). The underlying laminated black organogenic sediment (gyttja) and gray lake marl unit (Fig. 5A, unit C; see also Fig. 9B) represent an alkaline groundwater-fed shallow lake and marsh environment. Unit C overlies a unit of aeolian carbonate sands (unit B) up to 8 m thick, deposited during the Pleistocene, and the sequence is concluded by up to 2 m of clayey soils (unit A) overlying the bedrock (Fig. 5A; Rijsdijk et al., 2011).

Samples for radiocarbon dating (n = 27), of which 23 were successful, were obtained from the bonebed and just below it at three localities (TR0, CH5, and TR4) in sub-basin I (Fig. 2D; Table 1). These included bones (n = 7), a mollusk, and plant material (n = 12). These radiocarbon dates indicate that the bonebed is nearly isochronic and was formed approximately 4200 years ago (see
The calibrated radiocarbon dates overlap due to plateau effects, as also demonstrated by multiple dates on single samples (n = 4) (Table 1). A Bayesian based calibrated age-depth model indicates that the bonebed, including the underlying gytta and lake marl layer, formed within three centuries between 4370 and 4070 cal BP (Fig. 2D; De Boer et al., 2015).

FIGURE 5. A, top left panel shows a transverse cross-section through the Mare aux Songes, depicting the stratigraphy. Top right panel is an idealized succession of sediment layers at the former center of the paleolake (after De Boer et al., 2015): B, sediments exposed in 100 cm wide excavator scoop at TR1 at the former lake margin of sub-basin I: bone-supported bonebed, mixed with wood stems, and seeds; C, sediments exposed in 50 cm wide excavator scoop at TR4 in the middle of sub-basin II matrix-supported bonebed, with peat as matrix; the lower rectangular fossils are tree and root remains. Photographs by R.M.J.
On a surface of less than 15 m² at five excavation sites in the Mare aux Songes, ca. 10,000 bones were excavated, of which ca. 300 were from dodo. Assuming that a uniform distribution and density of animal remains were deposited in the marsh, it can be deduced that many thousands of vertebrates, including dodos, must have died in an area of only 1.8 ha, approximately 4200 years ago. The vertebrates represented in the deposit are dominated by two extinct species of giant tortoise (Cylindraspis), which are found alongside at least six unidentifiable passerine species, two species of macrochiropteran fruit bats (Pteropus), the dodo, and other birds; approximately 22 vertebrate species have been identified (Rijsdijk et al., 2011).

The formation of the multitaxic bonebed at Mare aux Songes came as a result of a coincidental interplay of environmental conditions. Sea level rise pushed upwards the groundwater table which led to the formation of a freshwater lake 4500 years ago (Fig. 4A), and the generally dry conditions prevailing in the lowlands attracted a rich fauna to the lake. Ongoing sea level rise led to a deepening of the lake, with water depths of up to 1 m reached 4200 years ago (Rijsdijk et al., 2009, 2011). This period, extreme droughts associated with a global climatic regime shift that was characterized by a monsoonal collapse (De Boer et al., 2014; see below) led to a critical lowering of groundwater and subsequent up-coning of the saline water wedge, especially during the dry seasons (Fig. 4B). During dry episodes, the freshwater lake began to contract, concentrating the living vertebrates around the shrinking water body and on the exposed soft lake surface.

At the same time, up-coning of the saline water wedge increased the salinity of the groundwater at sub-basin I, which likely became undrinkable for animals. Further evidence is derived from the presence of fungal spores of Sporothrix and diatoms, indicative of the presence of concentrated vertebrate excrement (nutrients) inducive to hypereutrophic water conditions, blooming of cyanobacteria, and poisoned water (De Boer et al., 2015; see below). These circumstances facilitated blooms of toxic cyanobacteria, as is evidenced by spikes of cyanobacterial pigments within the bone layer. Repetitive seasonal contamination and poisoning of the freshwater led to the accumulation of vertebrate remains at the Mare aux Songes. An anomalously high nitrogen isotope ratio measured in bone collagen from a giant tortoise subfossil from Mare aux Songes may be attributed to a urea-based physiological response to retain water during periods of drought, thus leading to nitrogen isotope enrichment in the bone tissue (Van der Sluijs et al., 2014).

Interdisciplinary analysis of deposits in a nearby coastal lake, Mare Tatos, 26 km NNE of Mare aux Songes (Fig. 2A), shows that anomalous decadal to centennial drought events occurred between 4350 and 4130 cal BP (De Boer et al., 2014, 2015). This period, also referred to as the ‘4.2 ka megadrought,’ has been recorded in other sites around the Indian Ocean and is associated with civilization collapses in Egypt, Pakistan, Mesopotamia, and eastern Africa (Gasse, 2000; Thompson et al., 2002; Marchant and Hooghiemstra, 2004; Staubwasser and Weiss, 2006; MacDonald, 2011). At both Mare Tatos and Mare aux Songes, the megadrought is also reflected in increased concentration of microcharcoal that indicates increased frequencies of natural fires. The megadrought was triggered by a global climatic regime shift that involved a monsoonal collapse that ultimately led to the current configuration and increased activity of the El Niño southern oscillation, a phenomenon that has prevailed for the last 4000 years (see De Boer et al., 2014). A high-resolution multiproxy analysis of a continuous core at TR4 in the Mare aux Songes (Fig. 5), supported by a Bayesian-based calibrated age-depth model (Blaauw and Christen, 2011), suggests that the megadrought was interrupted by two wetter periods. The bonebed postdates the second wet period and was formed during the third dry period from 4190 to ca. 4130 cal yr BP (De Boer et al., 2015). After the third drought, the lake at Mare aux Songes became permanently refilled and the lake floor was permanently immersed.

Ultimately, anomalous drought events were instrumental in the death of thousands of vertebrates through a combination of poisoned water conditions, drowning, and miring, within a period of less than 100 years.

TAPHONOMIC ANALYSIS

The majority of the skeletal material from the bonebed in sub-basin I is disarticulated and disassociated, but between 2005 and 2011 two partial associations were recorded: the pelvis and some leg bones of a dodo (Rijsdijk et al., 2009) and a carapace of the giant tortoise Cylindraspis inepta ( Günther, 1877) containing humeri and femora (Hume, 2014; Hume et al., unpubl. data). Most bones are chaotically mixed, with no clear preferential orientations (Fig. 6A, B; Rijsdijk et al., unpubl. data), but in

FIGURE 6. A, view from above of an in situ dodo pelvis in the Mare aux Songes bonebed. Photograph by Mikel R. Rijsdijk; B, mapped view of the in situ dodo pelvis, long bone (dark gray, red in online PDF), and tortoise long bone and carapace fragments (light gray, pink in online PDF). X-axis and Y-axis are coordinates in cm; three-digit numbers next to bones are depths of bone center relative to mean sea level in (m).

The bone material is attributed to suitable hydrological conditions, and, to a lesser degree, by our sampling technique using mechanical diggers (Meijer et al., 2012). These fractures were likely created by the dumping of basalt boulders in 1943 and, to a lesser degree, by our sampling technique using mechanical diggers (Meijer et al., 2012). The exceptional preservation of the bone material is attributed to suitable hydrological conditions, with groundwater rich in CaCO₃ as a result of upwelling through carbonate sands that underlie the bonebed. This created alkaline conditions in the peat which prevented geochemical dissolution of bone tissue; this factor was conducive to exceptional bone preservation (Rijsdijk et al., 2009; Van der Sluis et al., 2014).

In spite of chemical degradation, subfossil bone collagen was of suitable preservation for radiocarbon dating and stable isotope analyses, so that the diet of the dodo and both giant tortoise species could be interpreted. Both dodo and tortoises were predominantly herbivorous and mainly fed on C₃ plants and their products, e.g., seeds and fruits (Rijsdijk et al., 2009; Van der Sluis et al., 2014). Ancient mitochondrial DNA was characterized from the dodo head in the Oxford University Museum of Natural History (Shapiro et al., 2014). Ancient mitochondrial DNA was present in all subsequent dodo osteological work being based on incomplete, composite skeletal material (Owen, 1866a), made up of individuals of unknown age and sex (Livezey, 1993).

The almost complete disarticulation and disassociation of sub-fossil remains in the bonebeds at the Mare aux Songes resulted in all subsequent dodo osteological work being based on incomplete, composite skeletal material (Owen, 1866a), made up of individuals of unknown age and sex (Livezey, 1993).

TOWARDS AN ECOLOGICAL RECONSTRUCTION

The abundant admixture of plant debris in the bonebed, and the presence of plant microfossils and invertebrates, provides an unprecedented opportunity to reconstruct the paleoenvironment at Mare aux Songes. The near-coastal setting of the Mare aux Songes rock basin explains the gradient from saline to freshwater lakes from dry lowland to wet basins; these ecotones led to high plant diversity. The abundance of macro- and microscopic plant remains such as seeds, fruits, branches, stems, and tree roots reflects the richness of the flora at the time, as confirmed by macroscopic and microscopic analyses (Fig. 8). The bonebed contains high densities of seeds (10–30 mm), dominated by tambalacoque, Sideroxylon grandiflorum (Sapotaceae), bois d’olive, Cassine orientalis (Celastraceae), and several species of screw pine, Pandanus (Pandanaceae). The presence of S. grandiflorum is interesting, because this species was considered to be a montane endemic and never reported from the coastal lowland areas (Baidier and Florens, 2006; Florens et al., 2012). Wet forest species recorded at Mare aux Songes are confined to high rainfall sites today and are typical of a wet canopy forest plant community, especially Eugenia elliptica (Myrtaceae), Antirhea borbonica (Rubiaceae), and Canarium paniculatum (Burseraceae) (Florens et al., 2012). The finer sieve fractions (0.25–2 mm) of a 500-ml soil sample yielded >1000 seeds and other recognizable parts of plants. Microscopic analysis revealed that besides trees and shrubs, these could belong to smaller, non-woody plants. The seed assemblage of the bonebed confirms that the Mare aux Songes and surrounding area supported a wet forest plant community, which persisted in an otherwise dry coastal zone characterized by substantially drier vegetation, including characteristic
species like *Foetidia mauritiana* (Lecythidaceae) or *Terminalia bentze* (Combretaceae).

The peaty bonebed in sub-basin I contains stems, roots, and branches ranging in thickness from 10 to 300 mm (Fig. 8A). The local presence of at least 28 different taxa of dicot trees, shrubs, and one epiphyte has been revealed by microscopic analysis of ca. 350 samples of subfossil wood (Vernimmen et al., unpubl. data). Due to the predominantly wet, anoxic burial conditions, most anatomical characters of wood have been well preserved (Fig. 8B, C), enabling in some cases identification to species level. Several monocot stems were also found, and at least one type of palm was identified. The total wood assemblage includes taxa with either a broad ecological range or specific ecological preferences. These range from dry to wet forest and lowland to upland settings, which suggests that species composition at this low elevation site was diverse and very different from the present impoverished lowland forest on Mauritius (Vernimmen et al., unpubl. data). The fruiting bodies of a mushroom (species indeterminate), spores of other fungi, and a moss are also present in the deposit. These were presumably growing on the trunks of trees. Interestingly, many of the subfossil wood stems from a number of plant taxa show evidence of growth rings when cut in transverse section, which is indicative of seasonal differences in water availability (Vernimmen et al., unpubl. data; Fig. 8C).

The gyttja underlying the bonebed, the peat forming the matrix of the bonebed, and the peat capping the bonebed all contain pollen, spores, diatoms, and a suite of other microfossils. Continuous cores have been obtained from the bonebed and organogenic layers underlying it (Figs. 9A, B). Palynological studies of sediment cores indicate the presence of palm woodland and semidry coastal forest associations (De Boer et al., 2014, 2015). Palm woodland is represented by *Latania, Dictyosperma, Acanthophoenix*, and *Pandanus*; semidry forest by *Ficus, Eugenia, Sapotaceae, Terminalia bentze*, *Diospyros, Tabernaemontana*, and *Cassine orientalis*, small trees of *Gardenia* type, *Ixora, Zanthoxylum, Antidesma, Foetidia*, and *Hilsenbergia* type, and shrubs of *Dodonaea* and *Dombeya*. Taxa characteristic of palm woodland are better represented by pollen than by the analysis of fossil dicot wood and other plant macrofossils (Fig. 9C). We speculate that the eastern coast of the Mare aux Songs basins were predominantly affected by trade winds blowing landwards, delivering palm woodland pollen from the vegetation east of Mare aux Songs, whereas the wood fossils and larger seeds in the Mare aux Songs basins dominated by semidry forest taxa are all deposited from local standing vegetation. Although speculative, this may indicate that the vegetation around Mare aux Songs and further landward was dominated by semidry forest, whereas palm woodland occurred as a strip of vegetation between the lowlands and the coast (De Boer et al., 2015). The palm woodland may have provided an open vegetation community relatively easily accessible to non-volant vertebrates. The semidry forest must have been much denser, however, with a high trunk density that is attributed to the influence of frequent cyclones (Vaughan and Wiehe, 1937; Florens, 2008). This cyclone-resistant vegetation was described by the early colonists as dense and hard to penetrate (Moree, 1998; Cheke and Hume, 2008).

The pollen record revealed a remarkable lack of small shrubs and grasses in the Mauritian coastal forest understory vegetation until human advent (De Boer et al., 2014; Fig. 9C). Shrub and grass communities, increased biomass, and increased fire frequencies are generally associated with reduced or absent grazing regimes after megafaunal extinctions (Vaughan and Wiehe, 1937; Burney et al., 2003; De Boer et al., 2015). Seeds and fruits from un lignified plants, as well as wood samples from shrub-like species are, however,
identified. It is plausible, based on studies on the reintroduction program of giant tortoises on Ile aux Aigrettes (Griffiths, 2014), that high concentrations of giant tortoises kept the biomass in the understory to a minimum by grazing and browsing. Other indications that larger vertebrate fauna had an important role in the lowland forest ecosystems are based on (a) the presence of plant defense mechanisms such as spines on juvenile *Tectiphiala* palms; (b) the occurrence of heterophyll in several plant genera, where the juvenile leaves tend to be inconspicuous relative to the leaves of adult plants, to avoid being eaten (Cheke and Hume, 2008); and (c) the presence of many plant species producing cauliflorous fruits close to the ground, hence accessible to large flightless frugivorous vertebrates that would have served as seed disseminators (Florens, 2008). Given the former high abundance of giant tortoises on Mauritius (Cheke and Hume, 2008), they must have played a significant role in seed dispersal and in maintaining habitat heterogeneity through disturbances by grazing and browsing (Griffiths, 2014).

Because coprophilous fungal spores generally have a limited aerial dispersal range (Wood and Wilmshurst, 2012), the coprophilous fungal spores in the sediment cores of coastal sites suggest that herbivores lived around these sites (De Boer et al., 2014, 2015; Fig. 9C). The noted absence of fungal spores in the upland records suggests lower concentrations of these animals in montane forest (De Boer et al., 2013a, 2013b). Although large terrestrial vertebrates, e.g., dodos and tortoises, occurred in the uplands, heterophyll is very rare in the remaining forest patches, perhaps indicating that the main biotope for the populations of larger vertebrates was the coastal lowlands (Florens, 2002; Cheke and Hume, 2008; De Boer et al., 2014, 2015). The presence of insect remains in the Mare aux Songes, including
now extinct bird and giant tortoise specialist dung beetles (Scarabaeinae), which appear to have been confined to the coastal lowlands, further supports the notion that it was this ecotype that was the most vertebrate diverse prior to human arrival (Hume, 2009, 2012; Porch, unpubl. data).

RESILIENCE AND EXTINCTION: A CONCLUSION

The bonebed of sub-basin I at Mare aux Songes (Fig. 2C) provides a window of less than a century documenting the response of a coastal ecosystem to an extreme climatic event 4200 years ago. Although many thousands of vertebrates died within an area of 1.8 ha as a result of this pre-human-contact catastrophic event, the dodo and other vertebrates survived until the arrival of humans over 3500 years later.

The exact date of extinction of the dodo continues to be debated (Roberts and Solow, 2003; Hume et al., 2004; Mlikovský, 2004; Cheke, 2006; Cheke and Hume, 2008; Jackson, 2014), but what is certain is that during the second half of the 17th century, the dodo became extinct. After initially disappearing from the coastal lowlands, the last remnants of the dodo population were driven into remote areas of the island, where reproduction finally dropped to zero. Hunting of dodos by humans was probably negligible because the human population never reached more than a few hundred during Dutch occupation on an island 1865 km² in size, and only around 5% of the forests on the east coast had been cleared by the time of the dodo’s extinction (Moree, 1998; Floore and Jayasena, 2010; Winters and Hume, 2015). Furthermore, the interior of Mauritius was virtually impenetrable and unexplored (Hume and Winters, 2015). Moreover, historic reports indicate that the dodo was neither a prime food source nor hunting goal, and a refuse layer of thousands of animal remains found at Fort Frederik Hendrik never reached more than a few hundred during Dutch occupation on an island 1865 km² in size, and only around 5% of the forests on the east coast had been cleared by the time of the dodo’s extinction (Moree, 1998; Floore and Jayasena, 2010; Winters and Hume, 2015). Furthermore, the interior of Mauritius was virtually impenetrable and unexplored (Hume and Winters, 2015). Moreover, historic reports indicate that the dodo was neither a prime food source nor hunting goal, and a refuse layer of thousands of animal remains found at Fort Frederik Hendrik never reached more than a few hundred during Dutch occupation on an island 1865 km² in size, and only around 5% of the forests on the east coast had been cleared by the time of the dodo’s extinction (Moree, 1998; Floore and Jayasena, 2010; Winters and Hume, 2015). Furthermore, the interior of Mauritius was virtually impenetrable and unexplored (Hume and Winters, 2015). Moreover, historic reports indicate that the dodo was neither a prime food source nor hunting goal, and a refuse layer of thousands of animal remains found at Fort Frederik Hendrik never reached more than a few hundred during Dutch occupation on an island 1865 km² in size, and only around 5% of the forests on the east coast had been cleared by the time of the dodo’s extinction (Moree, 1998; Floore and Jayasena, 2010; Winters and Hume, 2015).

The results of the multidisciplinary investigation of the Mare aux Songes concentration Lagerstätte that resulted in the first scientific reconstructions of the dodo skeleton (Owen, 1866a, 1872; Newton and Gadow, 1893) underscore the importance of the Thirioux dodo finds. The Thirioux dodos comprise one almost complete, associated skeleton from a single individual (Port Louis specimen) and one partial composite skeleton (Durban specimen). Although the exact provenance of the Thirioux finds remains unknown (Claessens and Hume, 2015), these exceptional specimens provide important new information on dodo anatomy. These include the relative skeletal proportions from a single bird, and, collectively, they provide information on the anatomy of a near-complete skeleton, including multiple skeletal elements that were hitherto unknown or undescribed. Whereas the present memoir on the osteology of the dodo (Claessens et al., 2015b), based on the Thirioux specimens, opens up new lines of research on its morphology, physiology, and paleobiology, the Mare aux Songes provides complementary contextual ecological data and fundamental insights into the functioning of an insular ecosystem and its sensitivity to both environmental and human factors.

ACKNOWLEDGMENTS

We thank co-discoverers E. Lenting and C. Foo Kune for their invaluable support. We further thank M.-L. Foo Kune, P. La Hauze de la Louvière, S. Saumtally, O. Griffiths, A. Gill, R. Prys-Jones, G. Middleton, P. Moree, I. Prins, M.R. Rijsdijk, M. van der Meer, M. Schilthuizen, V. Tatayah, the volunteers of the Mauritius Wildlife Fund, the staff and technicians of the Natural History Museum of Mauritius, and the staff and technicians of OMNICANE Mon Tresor Team for their invaluable support. J. P.H. thanks R. Allain and C. Sagne (MNHN), S. Chapman (NMMUK), M. Brooke and M. Lowe (UMZC), and M. Nowak-Kemp (OMNH) for access to materials in their care. Field work and research was funded and supported by Omnicane, TNO—the Geological Survey of The Netherlands, the Treub Foundation for Research in the Tropics, World Wildlife Fund—The Netherlands, Deltares, Stichting Dodo Research, The Hague, Mauritius Museum Council, Hollandia Archaeology, Taylor Smith Group (Mauritius), Air Mauritius, Mauritius Sugar Industry Research Institute, Royal Society of Arts & Sciences of Mauritius, Mauritius Wildlife Foundation, and the Naturalis Biodiversity Center. Support for J.P.H. was provided by the Percy Sladen Centenary Fund, DIF, and Special Funds (Natural History Museum, London). E.J.d.B.’s work was carried out with the financial support from The Netherlands Organisation for Scientific Research (project number ALW 819.01.009). Support for L.C. was provided by the National Science Foundation (aves 3D project, DBI 0743272) and a College of the Holy Cross Research and Publication grant. H.J.M.M. received support from the Treub Foundation for Research in the Tropics, the Spanish Ministerio de Economía y Competitividad (CGL2011-28681), and the Generalitat de Catalunya (BP-B-00174 to H.J.M.M.). T.J.J.V. was funded by The Netherlands Organisation for Scientific Research (project number ALW 819.01.008) and SYNTHESIS Synthesis of Systematic Resources (project numbers BE-TAF-2974, GB-TAF-4289 and GB-TAF-5235). We appreciate the constructive and critical feedback by T. Worthy, G. Dyke, and J. Parish.
