Abstract

Background: Both genetic background and diet are important determinants of cardiovascular diseases (CVD). Understanding gene-diet interactions could help improve CVD prevention and prognosis. We aimed to summarise the evidence on gene-diet interactions and CVD outcomes systematically.

Methods: We searched MEDLINE® via Ovid, Embase, PubMed®, and The Cochrane Library for relevant studies published until June 6th 2022. We considered for inclusion cross-sectional, case–control, prospective cohort, nested case–control, and case-cohort studies as well as randomised controlled trials that evaluated the interaction between genetic variants and/or genetic risk scores and food or diet intake on the risk of related outcomes, including myocardial infarction, coronary heart disease (CHD), stroke and CVD as a composite outcome. The PROSPERO protocol registration code is CRD42019147031.

Results and discussion: We included 59 articles based on data from 29 studies; six articles involved multiple studies, and seven did not report details of their source population. The median sample size of the articles was 2562 participants. Of the 59 articles, 21 (35.6%) were qualified as high quality, while the rest were intermediate or poor. Eleven (18.6%) articles adjusted for multiple comparisons, four (7.0%) attempted to replicate the findings, 18 (30.5%) were based on Han-Chinese ethnicity, and 29 (49.2%) did not present Minor Allele Frequency. Fifty different dietary exposures and 52 different genetic factors were investigated, with alcohol intake and ADH1C variants being the most examined. Of 266 investigated diet-gene interaction tests, 50 (18.8%) were statistically significant, including CETP-TaqIB and ADH1C variants, which interacted with alcohol intake on CHD risk. However, interactions effects were significant only in some articles and did not agree on the direction of effects. Moreover, most of the studies that reported significant interactions lacked replication. Overall, the evidence on gene-diet interactions on CVD is limited, and lack correction for multiple testing, replication and sample size consideration.

Keywords: Diet, Gene-diet interaction, Myocardial infarction, Stroke, Coronary heart disease, Cardiovascular diseases

Introduction

Cardiovascular diseases (CVDs), including ischemic heart disease and stroke, are the leading cause of mortality and morbidity and are responsible for more than 18 million deaths globally in 2019 [1]. Several risk factors
have been associated with CVD incidence, diet being one of the most studied [2].

Contradictory findings have been reported on the role of micro-and macro-nutrients [3], specific foods [4], and dietary patterns [5] on CVD. These contradictions could be explained by the exclusion of genetic factors [6], which has a causal association with CVD onset [7–9]. Therefore, studying the combined impact of food intake/dietary patterns and genetic risk on CVD may improve CVD prevention and care precision [10]. Several studies have shown dietary components such as carbohydrates, micronutrients, vegetables, fatty acids, and alcohol to be linked with different genetic factors on CVD [11–17]. However, no systematic review summarising the evidence on diet-gene interaction on CVD has been published to date.

Previous systematic reviews published on the topic have primarily focused on evaluating gene-diet interactions on specific genes or have been restricted to particular dietary groups [18, 19]. In addition, understanding the association between pathological pathway factors requires distinguishing between statistical and biological interactions. In the context of gene-environment interaction (GxE), statistical interaction is understood as a deviation from the additivity of the effects of two exposures (genetic and environmental) on the outcome. In contrast, biological interactions are defined as the co-participation of two exposures in the same causal mechanism for the development of the outcome, regardless of their statistical ascertainment [20]. This paper focuses on statistical interactions, more frequently tested in the epidemiological literature [21]. Identifying exposure-disease interactions may help recognise groups at increased risk due to genetic susceptibility and help tailor prognostic tools and intervention strategies [22]. Therefore, we aimed to systematically summarise the evidence on gene-diet interactions and cardiovascular disease risk: CHD, myocardial infarction (MI), stroke, and CVD as a composite outcome.

Methods
The protocol of this systematic review was registered in PROSPERO (https://www.crd.york.ac.uk/prospero/daysplay_record.php?ID=CRD42019147031). For the conduct and reporting of this systematic review, we followed the steps proposed by Muka et al. [23] and Synthesis without meta-analysis (SWiM) in systematic reviews: reporting guideline [24].

Literature search
Studies were primarily identified through structured searches in MEDLINE® via Ovid, Embase, PubMed®, and The Cochrane Library, where we were searched for articles published until June 6th 2022 without language restriction. The search strategy was designed and implemented in collaboration with an experienced medical librarian (BM). This search strategy was designed based on subject headings (e.g. MeSH terms) and free text words related to three search domains: (1) diet, food, nutrition, (2) gene-diet interaction, and (3) cardiovascular diseases. Additional file 1: Appendix S1 contains the complete search strategies.

Study selection criteria
Studies conducted in the adult population were eligible for inclusion if (i) they were cross-sectional, case–control, prospective cohort, nested case–control or case-cohort studies, or randomised controlled trials; (ii) evaluated dietary intakes (micro- and macro-nutrients, specific food items, food groups, dietary scores, indexes, or patterns) Additional file 2: Table S1 [25]; (iii) evaluated incident or prevalent CVD as a composite outcome or any of the following outcomes: CHD, MI or stroke; (iv) evaluated the interaction between any genetic variant or genetic risk score (GRS) and food or diet intake; and (v) reported a statistical test for gene-diet interaction. We excluded epigenetic studies and publications that did not report a statistical test and p-values for the interaction between diet and genetics. Abstracts, cost-effectiveness studies, letters to the editor, conference proceedings, systematic reviews and meta-analyses were excluded.

Screening and study selection
All studies initially identified were screened independently by two authors applying the selection criteria. After that, the full texts of the studies that met the selection criteria were further evaluated independently by two authors. When there were discrepancies, the two authors reached a consensus or asked for the help of a third senior author.

Data extraction
Information from the included articles was registered in a pre-designed form; the data were first extracted by the first author and additionally reviewed and confirmed by a second author. We collected the author’s name, year of publication, country of origin of the population, ethnicity, setting, study design, name of the cohort, sample size, number of cases (CVD as a composite outcome, CHD, MI, or stroke), definition of the reported cases, percentage of women included, follow-up time, dietary intake evaluated, dietary intake measurements, genes, genetic variants assessed, minor allele frequency (MAF), and main findings. The estimates and p-values for gene-diet interactions were taken from the most adjusted model.
Assessing the quality of studies
We applied a quality score designed for gene-diet interaction studies [26]. The score evaluates eight items: interaction as primary study goal, test for interaction, correction for multiple testing, correction for ethnicity, Hardy-Weinberg equilibrium, test for group similarity at baseline, sample size, and sufficient details of the study procedure. Based on a range scale from –8 to 8, studies were rated as high quality (6 to 8 points), intermediate quality (2 to 5 points), and poor quality (–8 to 1 point). All the included studies were treated equally regardless of their quality.

Synthesis methods
A meta-analysis could not be carried out given the diversity of dietary exposures, gene-diet interactions, and the methodological heterogeneity of the included studies (different dietary exposures, gene variants and assessed interactions). We summarised the gene-diet interactions finding qualitatively and decided to group the included studies in two stages. First, we grouped the studies according to the assessed outcome into the following categories: CHD, stroke, and CVD as a composite outcome. Second, we presented the gene-diet interaction information according to five dietary intake groups (macronutrients, micronutrients, food and food items categories, other dietary components and dietary scores, indexes, or patterns) Additional file 2: Table S1 [25].

The principal characteristics and findings of the included studies are presented in tabular format. Additionally, we represented the interaction between dietary intake groups and genetic variants with CHD, stroke, and CVD through a heat map where p-values of diet-gene interactions are represented by colour intensity where the lowest p values have the most intense colour, and values near 1 have the lightest colour. All heat maps were created in R software environment for statistical computing [27] with RStudio environment [28] using the ggplot2 package [29]. To standardise the amount/frequency of alcohol intake reported in the interaction with an alcohol dehydrogenase 1C (ADH1C) variant, we transformed grams/day into drinks/week taking as reference the "standard" drink (14 g of pure alcohol) reported by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) [30].

Results
Study identification and selection
We identified 8700 articles, of which 5402 were unique citations. After screening titles and abstracts, we screened the full texts of 182 articles, of which 59 met the inclusion criteria and were included in the final analysis (Fig. 1). Of the included articles, 13 evaluated MI [16, 31–42], 18 evaluated CHD [11–13, 43–57], 12 evaluated stroke [14, 58–68], four examined composite CVD [15, 69–71], and 12 evaluated at least two of the following outcomes: CHD, MI, CVD or stroke [6, 17, 72–81]. The definition of all outcomes can be found in Additional file 2: Table S2.

Characteristics of all included studies and articles reporting significant gene-diet interactions
The general characteristics are described in terms of number of articles. Forty-five articles came from 29 unique studies; six articles involved multiple studies, and seven did not report details of their source population. Of the 59 articles, 24 (40.7%) were conducted in Europe, 21 (35.6%) in China, six (10.2%) in the USA, five (8.5%) in Costa Rica, one (1.7%) in Taiwan, one (1.7%) in Thailand and one (1.7%) was multicentre. The ethnicity most frequently reported was Chinese-Han in 18 (30.5%) articles, followed by Caucasian in eight (13.6%) articles, Hispanic/Latin American in five (8.5%) articles, and Mediterranean in four (6.8%) articles. The epidemiological designs of the included articles comprised 27 (45.8%) case–control studies, 19 (32.2%) prospective cohort studies, seven (11.9%) nested case–control studies, one (1.7%) case-cohort study, two (3.3%) randomised control trial studies, two (3.3%) family-based studies, and one (1.7%) cross-sectional study. The median sample size in the articles was 2562, ranging from 200 to 347,077 participants. Men and women were analysed in 53 (89.8%) articles; five (8.5%) articles analysed only men, and one (1.7%) article only women. The main interaction results among female study participants were presented in ten (17.0%) articles. The median age of participants among studies was 61 years, ranging from 57 to 72.4 (Table 1).

There were 52 genetic factors (GRS, genes, SNPs) and 50 different dietary exposures studied. A description of the dietary scores, indexes, or patterns reported can be found in Additional file 2: Table S2. The most investigated dietary component was alcohol, studied in 30 (50.8%) articles, and ADH1C studied in 7 (11.9%) articles. Regarding genetic information, 29 (49.2%) articles did not present MAF (Additional file 2: Table S2). Regarding outcome measurement, 28 (47.5%) articles included prevalent CVD cases, and 31 (52.5%) articles included the incidence of CVD cases. Overall, the median CVD events was 759, ranging from 72 to 10,372. Four (6.8%) articles replicated their findings in different samples (Table 1).

Characteristics of included articles reporting significant gene-diet interactions
In total, 31 articles reported significant gene-diet interactions. Among the articles reporting significant
interactions, the most frequent place of publication was China with 13 (41.9%) articles, followed by Europe with ten (32.3%) and Latin America with five (16.1%). The case–control design was reported in 22 (71%) articles; the median sample size was 3311, ranging from 200 to 77,004. Four (13%) articles evaluated the interaction between alcohol and the cholesterol ester transfer protein (CETP) rs708272 variant, being this interaction the most frequently evaluated.

Gene-diet interactions and coronary heart disease. Thirty three articles from 21 unique studies evaluated whether specific nutrients, foods or diets modified the association between genetic factors and CHD (Figs. 2

NR Not reported; BWHHS British Women’s Heart & Health Study; CCHS Copenhagen City Heart Study; EPIC European prospective investigation into cancer and nutrition cohort; FISSIC Fangshan/family-based ischemic stroke study in China; KHD Kuopio ischaemic heart disease risk factor study; NPHS II Second Northwick park heart study; TWB Taiwan Biobank; WHS Women’s Health Study.
and 3, Table 1) [11–13, 16, 31–57, 80, 81]. The most frequently evaluated dietary exposure and genetic variants were alcohol (n = 17) and ADH1C (n = 6), respectively. CETP TaqIB was the second most evaluated genetic variant; estimations for alcohol-ADH1C and -CETP interactions on CHD risk can be found in Table 2. The main findings regarding non-significant interactions in the macronutrients category were that PUFA intake did not interact with PLA2G4C, FADS1 or FTO variants on CHD risk. Micronutrients such as folate and vitamin B did not interact with the MTHFR 677CT variant. Other non-significant interactions were milk-LCT-13910, fried food-ALDH2, (dietary) cholesterol-APOE, alcohol-ADH1C, -CETP, -PON1, -PLAG2G7, -TFPI-2. Similarly, dietary scores did not significantly interact with GRS of HDL, LDL, triglycerides, or MI [6, 11–13, 17, 36, 40, 44–48, 52–57, 72, 76, 79, 81]. An overview of the non-significant interactions can be found in Figs. 2 and 3, and more details are provided in Additional file 2: Table S3. In the following paragraphs, we will discuss the findings of the articles that reported significant interactions.

Regarding macronutrients, in a Costa Rican case–control study including approximately 3800 patients, Allayee et al. [31] reported a significant (p = 0.015) interaction between arachidonic acid (AA) and 5-lipoxygenase (5-LO) promoter variants [31]. Consumers of ≥ 0.25 g/day of AA who carried one or two copies of the shorter three and four repeats of 5-LO had a higher MI odds ratio (OR) 1.31 (95% CI 1.07, 1.61) than consumers of < 0.25 g/day of AA who are 55 homozygote carriers. In comparison, among consumers of < 0.25 g/day of AA who were carriers of one or two copies of the shorter three and four repeats, lower odds was observed [OR 0.77 (95% CI 0.63, 0.94)] [31]. In the same study, Hartiala et al. found a significant (p = 0.005) interaction between PUFA and a variant of PLA2G4C (rs12746200) [36]. Subjects with high dietary n-6 PUFA intake (≥ 6.93 g/day) who were carriers of AG/GG genotype had lower odds for MI [OR 0.71 (95% CI 0.59, 0.87)] than AA homozygote subjects [36].

In a case–control study using Wuhan (China) data, Liu F et al. [49] found a significant (p = 0.028) interaction between PUFA and a variant of FADS1 (rs174547). Subjects in the lowest tertile of EPA and DHA intake who are

![Fig. 2 Findings for interaction between genetic variants and diet in relation to myocardial infarction. W = women, M = men, B = Both (Men and women)](image-url)
carriers of T alleles had higher odds of developing CHD [OR 3.04 (95% CI 1.94, 4.76)] and [OR 2.56 (95% CI 1.64, 3.98)], respectively, compared to subjects in the highest tertile of EPA intake and DHA consumption, who are also carriers of rs174547 C/C genotype. No association was observed in the middle tertile of EPA or DHA intake [49].

Regarding micronutrients, the Western Norway B-vitamin intervention randomised trial (WENBIT) prospectively evaluated interactions between folic acid, vitamins B12/B6 and an MTHFD1 variant (rs1076991) in 2381 participants [16]. In this trial, carriers of the rs1076991 T allele who received folic acid/vitamin B12 and vitamin B6 combined treatment had a hazard ratio (HR) for MI of 2.35 (95% CI 1.55, 3.57) (p = 0.047) when compared to the placebo group. On the other hand, no association with MI was observed in the groups who had vitamin B6 or folic acid/B12 separately [16].

In the food and food items categories, a case–control study using data from 52 countries (the INTERHEART study) [17], and a case–control study analysing data from a Hispanic population [33], reported interactions between high vegetable intake and four variants (rs10757274, rs2383206, rs10757278, rs1333049) of the chromosome 9p21 [17] and the Glutathione S-transferase theta 1 (GSTT1) gene variants [33]. Subjects whose vegetable intake was classified in the highest tertile who were carriers of the functional GSTT1*1 allele had lower odds for MI [OR 0.70 (95% CI 0.58, 0.84)] compared to those whose intake was classified in the lowest tertile (p = 0.006) [33]. In contrast, carriers of risk alleles of 9p21 variants had a lower incidence of MI among participants who consumed vegetables daily (p < 0.008) [17]. However, the interaction with 9p21 variants was not significant when restricted to cooked vegetables [17].

In a case–control study using data from the same Hispanic population mentioned above, Cornelis et al. reported a significant (p = 0.04) interaction between coffee consumption and CYP1A2 variants on MI risk [34]. The consumers of ≥4 cups/day of coffee carrying the rs762551 variant had higher odds of MI [OR 1.64 (95% CI 1.1, 2.34)] [34] compared to those consumed <1 cup/day. Conversely, a study from Taiwan Biobank (TWB) found a significant (p = 0.03) interaction between coffee
Table 2: Estimates of the interaction between alcohol intake and ADH1C variants on CHD risk

| Author           | Categorization of Alcohol (Drinks/week) | No. of Events | Association measure | Gene, variant, and genotypes Estimate (CI 95%) | Interaction P-value |
|------------------|----------------------------------------|---------------|---------------------|-----------------------------------------------|--------------------|

consumption and a tribbles pseudokinase 1 (TRIB1) variant rs17321515 on CHD. Those who drank coffee and were carriers of the GG genotype had reduced odds of CHD [OR 0.62 (95% CI 0.45, 0.85)] compared with non-coffee drinkers [50].

Concerning other dietary components, in a case–control study from the Etude Cas-Témoin de l’Infarctus du Myocarde (ECTIM) (n = 724), alcohol consumption significantly (p < 0.005) interacted with the CETP TaqIB variant (rs708272). Subjects who consumed 50 g/day or more alcohol and were TaqIB B2B2 homozygotes had a lower odds of MI [OR 0.75 (95% CI 0.39, 1.52)] compared with those who consumed < 50 g/day [51]. Jensen et al. [12] reported a significant interaction between alcohol and the same variant [12, 45, 51]. Similarly, a nested case–control study from the Physicians’ Health Study (n = 1166) reported a significant (p = 0.01) interaction on MI risk between alcohol consumption and ADH1C. The lowest risk was observed in those who consumed ≥ 1 drink per day and carried ADH1C (r2 γ2), compared with those who consumed ‘1 drinks per week [RR 0.14 (95% CI 0.04, 0.45)] [37]. Other studies evaluated the interaction between alcohol and ADH1C but reported no significant interactions (Table 2 and Additional file 2: S3).

Han Chinese population matched case–control studies found increased risks of MI due to the interaction of alcohol consumption with the CXCL12 rs1746048 and PCSK9 rs11206510 variants [32, 41] (p < 0.001). Participants with the rs1746048 CC genotype and rs11206510 TT genotype consuming 0–250 g/day of alcohol had an MI OR of 14 (95% CI 3.2, 61.4) and 9.63 (95% CI 3.7, 24.9), respectively [32, 41], compared to non-drinkers. By contrast, within the same categories of alcohol intake, carriers of the Cx37 variant rs1764391 with CC genotype had an OR 0.54 (95% CI 0.31, 0.9) [38]. An increased odds of MI was observed between those consuming ≥ 250 g/ day alcohol who carried the rs1764391 CC genotype, rs1746048 CC genotype, and rs11206510 TT genotype, with ORs of 32.7 (95% CI 4.4, 241.6), 24.0 (95% CI 4.9, 116.3), and 14.0 (95% CI 5.1, 42.1), respectively [32, 38, 41]. Additionally, in the same population, carriers of the SLC22A3 variant rs539298 with AG/GG genotype who reported alcohol drinking had an OR 0.53 (95% CI 0.37, 0.77), compared with no drinkers [80].

A case–control study by Zheng et al. [42] analysed data from a Hispanic population and reported a significant (p = 0.03) interaction between SSB consumption and the GRS of 9p21 variants (rs4977574, rs2383206, rs1333049). The OR of an MI incident (per allele risk of GRS) was 1.00 (95% CI 0.94, 1.07) in participants with SSB intake of <1 serving/day, 1.07 (95% CI 0.99, 1.14) in participants with an intake of 1–2 servings/day, and 1.12 (95% CI 1.05, 1.20) in participants with an intake of > 2 servings/day [42]. Additionally, a case–control study from the Nanning province (China) showed that participants who consumed alcohol and were carriers of the mevalonate kinase (MVK) variant rs3759387 with AA/AC genotypes had reduced odds of having CHD [OR 0.66 (95% CI 0.45, 0.96)] [43]. On the contrary, a study performed in Wuhan (China) found a significant (p = 0.001) interaction between alcohol intake and Interleukin-6 (IL-6) variant rs1800795; current drinkers who were carriers of the rs1800795-C allele had an OR of 3.17 (95% CI 2.20, 4.24) [43], compared to never-drinkers.

In terms of dietary scores/indices, in a prospective analysis comprising 77,004 participants from the UK Biobank, Livingstone et al. [77] reported a marginal (p = 0.049) interaction between Healthy Diet Indicator (HDI) (Additional file 2: Table S2) and GRS-CVD.
addition, the study found a significant ($p = 0.026$) interaction with the MDS and GRS-CVD on the risk of MI (Additional file 2: Table S2); individuals adhering to the Mediterranean diet (high MDS) with higher genetic CVD risk had a stronger risk reduction [HR 0.91 (95% CI 0.85, 0.97)]. In comparison, there was no evidence of an interaction of MDS on MI in participants with low GRS-CVD [HR 1.03 (95% CI 0.94, 1.12)] [77].

Gene-diet interactions and stroke

Twenty two articles from 14 unique studies evaluated whether specific foods or diets modified the association between genetic factors and stroke (Fig. 4, Table 1) [6, 14, 58–66, 73–79]. Non-significant interactions were reported for alcohol intake and APOE, IL-8 variant, PDE4D, DGAT2, CONNEXIN37 genes. Similarly, different dietary scores did not interact with CLOCK gene variants or GRS-CVD and GRS-stroke [61, 64–66, 68, 73, 76, 78], Additional file 2: Table S3.

In the macronutrients category, the MDC cohort study evaluated interactions between fatty acids and the FADS1 rs174546 variant. This study found that only the interaction between ALA and FADS1 rs174546 TT genotype was significant ($p = 0.03$). Participants in the higher ALA consumption quintile carriers of TT genotype had a decreased risk of stroke [HR 0.50 (95% CI 0.27, 0.94)], compared to carriers of the TT genotype in the lowest quintile of ALA intake. At the same time, no association was observed in CC and CT genotypes in the other quintiles [6].

Within the food and food items categories, the FISSC found a significant ($p = 0.006$) interaction between the egg intake and ABCA1 variant (rs2066715) [63]. In the same study, a significant interaction between vegetable intake and the PON1 rs662 variant on the risk of stroke was found. Each standard deviation increment in
vegetable intake was associated with a 40% reduction in the risk of stroke among carriers of the PON1 rs662 AA genotype. On the contrary, each standard deviation increment in vegetable intake was associated with a 51% increased risk of stroke among rs662 GG carriers; after adjustment for fruit intake, the interaction was not significant \((p = 0.12)\) [60].

Concerning other dietary components, a case–control study from Beijing in China found a significant \((p = 0.001)\) interaction between alcohol and CRP variant rs3093059. Drinkers with the rs1800947 GC [OR 11.11 (95% CI 1.22, 100.45)] and GG genotypes [OR 2.99 (95% CI 1.73, 5.19)] had an increased odds of having a stroke compared with non-drinkers and carriers of GG genotype. On the other hand, non-drinkers with the rs1800947 GC genotype had an OR of 2.95 (95% CI 1.05, 8.29) [58]. Similarly, another case–control study in a Chinese Han population found a significant \((p = 0.003)\) interaction between drinking status and the Fgβ 148CT variant. Drinkers who are also carriers of CT/TT genotype had increased odds of having a stroke \((OR 22.7 (95\% CI 2.95, 173.76)\) compared to non-drinker carriers of the CC genotype [59]. Another case–control study from the Community Hypertension Survey in the Chinese city of Yixing found a significant \((p = 0.048)\) interaction between drinking status and rs852426 β-actin (ACTB) variant on stroke risk \([HR 0.54 (95\% CI 0.29, 0.99)]\) [14]. Another Han population case–control study found a significant \((p = 0.001)\) interaction between alcohol status and rs4846049. Drinkers with rs4846049 CA/AA genotype had an OR of having a stroke of 3.12 \((95\% CI 1.83, 4.45)\) compared with never drinkers and rs4846049 CC genotype. None of the other MTHFR variants evaluated significantly interacted with alcohol [66].

In the category of dietary patterns, the PREDIMED trial found a significant \((p = 0.04)\) interaction between the Mediterranean diet and the LPL rs13702 variant. Participants assigned to the intervention group (Mediterranean diet plus supplementation with extra-virgin olive oil and nuts (30 g/day)) who were carriers of the C allele had a reduced stroke risk \([HR 0.58 (95\% CI 0.37, 0.91)]\) in comparison to the TT genotype. At the same time, no association was reported for the control group (fat intake reduction) [74]. Finally, Helstrand et al. [76], analysing data from the MDC cohort, reported a significant \((p = 0.04)\) interaction between diet quality index and GRS-LDL-cholesterol on stroke risk (Additional file 2: Table S2). Participants with low/medium diet quality had a HR of 1.09 \((95\% CI 1.03, 1.16)\) per standard deviation of increment of GRS-LDL-cholesterol [76].

Diet-Gene interactions and cardiovascular diseases as a composite outcome

Eight articles from four unique studies evaluated diet-gene interactions on cardiovascular diseases as composite outcome \([6, 15, 56, 69, 70, 75, 76, 79]\) (Fig. 5, Table 1). Non-significant interactions were reported for drinking status-ADH1C variant, and diet quality with GRS of HDL, -LDL and -triglycerides \([6, 69–71, 75, 76]\), Additional file 2: Table S3.

In the macronutrients category, a borderline \((p = 0.06)\) interaction was reported between ALA/LA intake ratio and the FADSI variant on CVD incidence. No statistically significant interaction was observed with any of the other fatty acids evaluated [6]. Regarding micronutrients, neither folate nor vitamin B intake interacted with MTHFR variants on CVD risk [79].

Regarding food and food items categories, Hindy et al. [70], analysing data from the MDC cohort, reported a significant \((p = 0.043)\) interaction between vegetable intake and chromosome 9p21 variant rs4977574. When the analysis was restricted to medium or high tertile of vegetable intake, carriers of the G allele had an increased risk of CVD with HR 1.27 \((95\% CI 1.17, 1.38)\) and 1.19 \((95\% CI 1.08, 1.30)\), respectively, compared to AA homozygote genotype. No interaction was reported for fruit intake [70]. Moreover, Sonestedt et al. [15], in another analysis of the same MDC cohort, found no interaction between vegetable intake and GRS of HDL cholesterol, LDL cholesterol or triglycerides on CVD risk [15]. Additionally, in the UK Biobank, there was no interaction between coffee intake and CYP1A2 genotype or with a GRS of caffeine metabolism on CVD risk \((p > 0.53)\) [71].

Concerning other dietary components, in the MDC cohort, a significant \((p = 0.029)\) interaction was found between wine consumption and chromosome 9p21 variant rs4977574 on CVD risk. However, the effect was limited to the non/low wine intake tertile in the stratified analysis. In that group, carriers of the G allele had an increased risk of CVD \([HR 1.23 (95\% CI 1.14, 1.34)]\) compared to the AA homozygote genotype. At the same time, no association was observed when total alcohol intake was evaluated [70].

Risk of bias of the included studies

Twenty one (35.6%) articles were classified as high quality, 36 (61.0%) as intermediate quality, and two (3.3%) as poor quality. Small sample size, lack of correction for multiple testing (11 (18.6%) articles adjusted for multiple comparisons), lack of generalisation (e.g., no different ethnicities being represented) often limited the methodological quality (Additional file 2: Table S4), a report of the SWiM items can be found in Additional file 2: Table S5.
Discussion

Of the 59 included articles, 32 reported a statistically significant gene-diet interaction. Dietary and genetic exposure were very heterogeneous, which precluded us from conducting a meta-analysis of the results. CETP and alcohol dehydrogenase (ADH1C) variants were the most frequently assessed and were shown to interact with alcohol to modify the risk of MI and CHD. Other studies investigating plausible biological interactions such as FADS gene and fatty acids interactions, vitamin B6, vitamin B12 and folic acid did not show consistent findings. While several studies investigated the interactions between genes and dietary factors on CVD risk, the current literature is limited and not consistent in showing gene-diet interactions with clinical and public health impacts, mainly because the reported positive findings were derived from case–control studies and lacked replication.

Previous systematic reviews on gene-diet interactions and CVD have primarily focused on specific genes or diets. In contrast, our study provides a comprehensive assessment of all genes and dietary exposures interactions on CVD. Similar to previous findings, we identified a lack of consistency in the results of interaction studies [19, 82]. In this review, the lack of reproducibility in the genetic-dietary variables operationalisation and the different levels of validation and reliability of the used dietary questionnaires could have led to an increased risk of exposure misclassification. This risk could be more relevant in case–control studies, in which recall bias could occur differently between cases and controls since the cases are aware of the condition [83]. Additionally, misclassification due to genotype errors can be another source of bias. Genotyping error has been reported to vary between about 1% and 30%, and its extension is related to variations in DNA sequence, quality of the analysed DNA, biochemical artefacts and human factors [84].

Another methodological concern of studies looking at gene-diet interaction and CVD is the sample size of the studies. Low statistical power leads to a reduced capacity to detect interactions. Genotyping errors, allele frequency and the precision of the dietary exposure and outcome measures are some of the criteria that...
researchers should consider when calculating adequate sample size to evaluate interactions [85]. Nevertheless, most of the studies included in this paper were secondary analyses, and there was no information on whether studies had enough power to detect an interaction. It has been estimated that detecting the interaction between two binary exposures requires a sample size four times larger than that required to detect main associations of the same magnitude [86].

Similarly, studies with 95% of power and a MAF of 20% looking for interactions of 1.5 of magnitude between genetic variants and continuous exposures require a sample size of up to 30,906 subjects [86]. In this paper, 50% of the included studies had a sample size below 2562 individuals. Just four studies exceeded 30,000 participants, and two of them did not clearly state the MAF frequency [75, 77]. The lack of information on the main factors involved in calculating power in almost half of the included studies limited the evaluation of their sample robustness for detecting gene-diet interactions. Notably, of the four studies that exceeded 30,000 participants, only one found a significant interaction [77].

Comparing specific foods and gene variants generates multiple comparison scenarios that could increase the Family-wise error rate [87], where the probability of false-positive findings increases with each additional comparison [88]. Therefore, including a correction for multiple testing is a suitable approach in studies with these phenomena, even though in this study, just two studies stated a correction for multiple comparisons in their methodology [17, 78].

Alcohol was the most evaluated exposure; its interaction with the CETP polymorphism (rs708272) was not consistent for CHD. The results did not agree with the direction of reported interactions, and most of the interactions lost statistical significance in the sex-stratified analysis. The low prevalence of alcohol intake could explain this difference and hypertriglyceridaemia in the populations evaluated. [12, 45]. In addition, only two studies included incident cases. However, the protective effect of the CETP-alcohol interaction could be related to the synergy between the B2 allele of CETP, which is associated with lower plasma CETP activity [89], and the inhibitory effect of alcohol on CETP activity [12]. Both may increase HDL concentrations, decrease LDL and VLDL fractions, and, consequently, reduce CVD risk.

Similarly, concerning lipid metabolism, a matched case–control study reported an interaction between the ADHIC variant and alcohol intake that decreases the incidence of MI in men who drank daily and were homozygous for the y2 allele. Carriers of the y2 allele are slow metabolisers of alcohol, which could enhance the beneficial effect of moderate alcohol consumption on lipid metabolism. In addition, the study stated that up to 50% of the observed decrease in MI risk could be attributed to increased HDL levels [37]. However, findings on ADHIC polymorphism and alcohol interactions were not homogeneous, and five studies did not report significant interactions, even though different alcohol intake categories were tested among these studies [11, 13, 39, 47, 55]. These findings suggest that the interactions between alcohol consumption and the ADHIC variant on CVD might be mediated through mechanisms independent of HDL cholesterol [69].

The increased risk of MI in the WENBIT trial could be explained by the association of vitamin B6 and folate intake with elevated hepatic adenosylmethionine (SAM). SAM is an inhibitor of betaine-homocysteine methyltransferase, an enzyme that regulates hepatic lipids and induces ApoB expression and VLDL assembly. Furthermore, the MTHFD1 variant (rs1076991) minor T-allele has been associated with an approximately 62.5% drop-in transcription rate of the MTHFD1 enzyme, which could also be associated with intercellular SAM accumulation, conditions that lead to dyslipidaemia and the consequent increased CVD risk [16]. However, when MI was evaluated as part of CVD composite outcome or individually in WHS, the folate or B-vitamin—MTHFD1 interaction was not found [79]. It is important to note that meta-analyses of the association of MTHFR and CVD have found substantial geographical heterogeneity and null associations for MTHFR and CVD in North American populations, such as women involved in the Women's Health Study [79].

Strengths and limitations
A significant strength of this paper is the comprehensive search strategy implemented to retrieve gene-diet interaction studies. We included all food and dietary exposures and epidemiological designs, providing a comprehensive overview of the literature. Also, we provided a critical evaluation of the quality of the current evidence on the topic. In addition, the included studies point to several biological mechanisms that could underlie the differences in the susceptibility to food/diet exposures and cardiometabolic diseases. However, it is a limitation for this study that, so far, no gene-diet interaction critical appraisal tool has been developed. This tool could standardise the evaluation of the studies' risk of bias and methodological quality, identifying the most significant weaknesses. Other issues were the lack of replication in the evaluation of interactions, few studies evaluated the same dietary and genetic exposures (SNP, GRS). Moreover, authors evaluating the same genetic variants used different genetics models (e.g. recessive model, co-dominant model or dominant model). This heterogeneity
limited the synthesis of the findings and are also a great weakness for the progress in the identification of population at higher risk of cardiometabolic diseases due to their genetic background and food/diet exposures.

**Future research and implications**

Identifying the mechanisms underlying gene-diet interactions is a priority; therefore, variants identified in GWAS are required to be investigated in functional studies, a challenge that could benefit from computational modelling. In addition, studies assessing interaction should provide more information on the origin of biases in the genetic exposures assessed (genotype misclassification, population stratification). Future studies should analyse samples with a suitable size for evaluating interaction hypotheses, for which data sharing through consortia may play a crucial role. Replication in independent samples is also essential, for which the selection of a single reference group is a critical factor in facilitating the comparability among studies. Besides, studies should provide information on the size of interactions and the effects of gene and dietary exposures separately and in joint effect. Even though it was out of the focus of the current study, recent studies have shown that environmental factors including dietary compounds may modulate gene expression, influence DNA methylation processes, and regulate histone and microRNA assembly, which on the other hand may affect risk of diabetes and cardiovascular disease [90]. Therefore, multi-omics approaches investigating how genetics and epigenetics (and other omics pathways) interact with diet in affecting risk of cardiometabolic diseases should be considered in the future. Finally, the use of prospective data that allows the evaluation of gene-diet interactions effects on incident outcomes should be prioritised.

**Conclusion**

Current evidence for gene-diet interaction in CVD is limited, as most interactions have been evaluated in single studies, without multiple correction testing, and mainly in European ethnicities; furthermore, studies have limited information to assess the robustness of sample size. Therefore, data-sharing platforms that combine large studies are needed to address current methodological problems and facilitate replication. In addition, priority should be given to the inclusion of diverse ethnicities and sample size-focused reporting to provide more conclusive evidence of gene-diet interaction with CVD that allows the development of nutritional personalized interventions.

At BMC, research is always in progress. Learn more biomedcentral.com/submissions

Ready to submit your research? Choose BMC and benefit from:

• fast, convenient online submission
• thorough peer review by experienced researchers in your field
• rapid publication on acceptance
• support for research data, including large and complex data types
• gold Open Access which fosters wider collaboration and increased citations
• maximum visibility for your research: over 100M website views per year
