Transferable diseases are deadly enemies of the overall population and tuberculosis (TB) is among the highest of ten causes of global death. TB is an infectious disease caused by *Mycobacterium tuberculosis* . In 1882, the microbiologist Robert Koch described the tubercle bacillus, at a time when one of every seven deaths in Europe was affected by TB. In 2014, there was an estimated 9.6 million TB cases, including 5.4 millions of men, 3.2 millions of women and 1.0 million children. There were 1.5 million deaths (1.1 million among HIV-negative people and 0.4 million among HIV-positive people) reported due to TB. The number of deaths caused by TB is highly unacceptable. With a timely diagnosis and precise treatment, almost all TB patients can be cured. STN controls the bacterial growth by repairing cell membranes and inhibiting protein synthesis. Currently, STN is being extensively applied in infectious endocarditis, plague, and veterinary medicine to get rid of bacterial infectious diseases. Hence, its chemical synthesis and detection from biological fluids and pharmaceuticals are of utmost importance in the field of chemistry. In recent years, several techniques have been applied for STN detection in pharmaceuticals and biological fluids, such as high-performance liquid chromatography (HPLC), ion-exchange-high-performance thin-layer chromatography (HPTLC), liquid chromatography-tandem mass spectrometry (LC-MS/MS), and colorimetric visualization. Although there have been significant improvements in these techniques, their application is limited due to exclusive equipment and substances, a complicated wash process and time consuming. An electrochemical investigation is a rapid, powerful technique for identifying such molecules due to its benefits of simple process, low cost, and high sensitivity in vivo determinations. Therefore, the detection of STN in biomaterials through electrochemical and other techniques are mainly attracted to researchers. However, there are some challenges while detecting STN in biomaterials due to its low accessibility, partial stability in temperature, pH dependence and biological solvents. As reported by Ghanbari and co-workers, a novel method employs gold nanoparticles and thiol graphene quantum dots as electrode modifiers for the determination of STN. The sensor showed a linear rage 0.1 to 700.00 pg mL⁻¹, with a limit of detection (LOD) 0.033 pg mL⁻¹. Roushani and co-workers

Cytochrome c/Multi-walled Carbon Nanotubes Modified Glassy Carbon Electrode for the Detection of Streptomycin in Pharmaceutical Samples

Rajasekhar CHOKKAREDDY,* Gan G. REDHI,* and Karthick THANGAVEL**

*Department of Chemistry, Durban University of Technology, Durban-4000, South Africa
**Department of Physics, School of Electrical and Electronics Engineering, SASTRA Deemed University, Thanjavur, 613401, Tamil Nadu, India

A novel electrochemical glassy carbon electrode modified with a multi-walled carbon nanotube, cytochrome c (Cyt c) and zinc oxide nanoparticles (ZnONPs) was fabricated to increase the sensitivity of electrode for the detection of streptomycin (STN) in certain pharmaceutical samples. Cyclic voltammetry (CV) and differential pulse voltammetry techniques were used for an electrochemical characterization of the electrode. Furthermore, the electrochemical biosensor construction phases were examined by using X-ray diffraction (XRD), transmission electron microscopy (TEM) and Fourier-transform infrared spectroscopy (FTIR). Under the optimal experimental conditions, the electrode offers a high selectivity and sensitivity signaling in the co-existence method of STN with the linear concentration ranging from 0.02 to 2.2 μM. The detection limits (LOD) and limit of quantification (LOQ) were found to be 0.0028 and 0.0562 μM, respectively. The fabricated sensing electrode has good stability, reproducibility and sensitivity towards STN in the pharmaceutical samples. Preliminary determinations of binding sites within the specified grid box size, which covers both Cyt c and STN, were done by molecular docking analysis. Moreover, density functional theory (DFT) computations were performed to provide insightful information into the optimized geometry of STN.

Keywords Cytochrome c, streptomycin, different pulse voltammetry, molecular docking, DFT computations

(Received August 7, 2020; Accepted February 18, 2021; Advance Publication Released Online by J-STAGE March 5, 2021)
have developed an electrochemical aptasensor for detecting STN in milk and blood serum, by using a gold electrode fabricated with a thin mesoporous silica film and silver nanoparticles. The aptasensor shows a linear range 1 fg mL\(^{-1}\) to 6.2 ng mL\(^{-1}\), with a LOD of 0.33 fg mL\(^{-1}\).\(^1\) Zarei and co-workers have reported a novel sensor for determining STN in urine and plasma, by using a molecularly imprinted composite through the electro oxidation of 3-methyl-4-nitrophenol on GCE in the presence of Au(III). The proposed sensor shows a linear detection range of 0.35 – 4.5 and 4.5 – 250 pM, with an LOD of 0.25 pM.\(^2\) Akbarzadesh and co-workers have developed an electrochemical sensor for the detection of STN in the presence of oxytetracycline in milk samples. This determination exhibited two linear dynamic ranges, 0.4 to 240.0 and 240.0 to 720.0 nM, and a detection limit of 0.17 nM for STN.\(^3\) However, the above described electrochemical sensors for STN determination were based on complex procedures for the synthesis of nanomaterials, and were often modified using multiple routes in plasma and urine samples only. In this investigation, we developed a novel sensor for determining STN in pharmaceutical samples. Thus, novel and easier routes enabling the fabrication of electrochemical sensors procedures are highly desired for pharmaceutical samples. To overcome the above-mentioned challenges, an alternative sensing approach employing a hybrid material platform (like the one proposed in this work "Cyt c-ZnONPs-MWCNTs-GCE") is essential. Metal oxide nanoparticles (ZnONPs, TiO\(_2\) and Fe\(_2\)O\(_3\)) are widely used in the sensor hybrid material platform due to their high catalytic activity and large specific surface area. ZnONPs, TiO\(_2\) and Fe\(_2\)O\(_3\) are semiconductors with respective band gap energy of 3.0, 3.33 and 3.36 eV at room temperature.\(^4\) The size and morphology of ZnONPs depends on the content of the precursors used in the synthesis of these NPs.\(^5\) Multi-walled carbon nanotubes (MWCNTs) are broadly used as an electrode coating material as they have a large specific surface area, electrochemical bond expansion, good adsorption properties, and they are chemically and thermally stable enough.\(^6\) Hence, they can be used to improve the sensitivity of the electrochemical response and making it appropriate for fastening the nanoparticles onto the outer surface of MWCNTs. Cytochrome c (Cyt c) is a highly water-soluble hemeprotein found to loosely bind with the inner membrane of the mitochondrion. Cyt c is an extremely conserved hemeprotein with a molecular weight of approximately 12 kDa. It consists of a single 104 amino acid peptide with a single heme group, which is attached to Cys\(^{48}\) and Cys\(^{17}\) through covalent bonds.\(^7\) The Cyt c reacts with several organic and inorganic radicals\(^8\) and its unique electron transfer property can be used to construct an electrochemical biosensor. The Cyt c carries an electron and is responsible for a redox mechanism in cell biology as well. Therefore, Cyt c is also used as one of the electrode coating materials in our study. Finally, an effective Cyt c-based electrochemical biosensor was prepared on the surface of glassy carbon electrode (GCE) modified with MWCNTs and ZnONPs nanocomposite by an enzyme immobilization procedure. The electrochemical properties and analytical performance of the electrode were examined by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) methods. The investigational parameters affecting the detectability of the sensor for STN were optimized in detail. The active binding sites between STN and Cyt c were also predicted by molecular docking analysis. The local reactivity descriptors of STN were predicted using DFT calculations to obtain more structural insights. The analytical applications and selectivity performance of the sensing electrode were examined.

## Experimental

### Reagents and chemicals

The essential chemical supplements, such as sodium hydroxide, sulfuric acid, \(N,N\)-dimethyl formamide (DMF), disodium hydrogen phosphate, sodium dihydrogen phosphate, ethanol (99.9%), zinc chloride, uric acid, glucose, sodium chloride, glutamic acid, folic acid, sucrose, potassium bromide, ferrous sulfate, nickel nitrate, potassium sulphate, potassium hydroxide and acetic acid, were obtained from Capital Lab Supplies (Durban, RSA). Pure analytical-grade of streptomycin and MWCNTs (outer diameter 7 – 15 nm and length 0.5 – 10 m) was from Sigma Aldrich (Durban, RSA). Nitrogen gas with 99.9% purity was supplied by AFOREX (Durban, South Africa). Deionized water was produced from an aqua MAXTM-basic 360 series water distillation scheme, and was provided by Trilab Support (Durban, RSA). The alumina polishing cloth (53 μm) was provided by Metrohm (Durban, RSA). All samples and reagents were prepared with deionized water.

### Preparation of ZnONPs

In order to synthesis ZnONPs nanoparticles,\(^9\) 5.45 g of ZnCl\(_2\) (0.2 M) was dissolved in 200 mL ethanol and the resulting solution was constantly stirred for 30 min with the help of a magnetic stirrer. In addition, 1.12 g (0.4 M) of KOH was dissolved in 50 mL of ethanol to prepare an aqueous ethanol solution of KOH. Then, a 0.4 M KOH solution was added dropwise without disturbing the solution much (allowed dropwise by touching the walls of the vessel) to a solution of completely dissolved ZnCl\(_2\) for 1 h. The final solution was covered and allowed to settle down overnight. The precipitate of ZNONPs was separated carefully after extracting the supernatant solution and undergoing a centrifuging process of the remaining solution for 5 min. Furthermore, the precipitate of ZnONPs were cleaned with double-deionized water three times, and then dried in an oven at 60°C for 1 h, in order to convert the Zn(OH)\(_2\) into ZnO.

### Fabrication of GCE with MWCNTs and ZnONPs

A glassy carbon electrode was carefully polished with 0.3 μM aluminium polishing cloth and rinsed with double-deionized water. Later, GCE electrode were washed with double-deionized water and dried at room temperature for 10 min. Thereafter, 0.20 mg of MWCNTs were dispersed in 5 mL of a DMF solution, and then the resulting mixture was sonicated for 60 min by using an ultra sonicator. In addition, 0.40 mg ZnONPs and 0.40 mg of MWCNTs were spread into 20 mL of DMF, and it obtain a gray suspension. Then, 10 μL of ZnONPs-MWCNTs was drop casted onto the polished surface of a GCE electrode and kept for drying in an oven at 40°C for about 20 min. The prepared ZnONPs-MWCNTs-GCE was then allowed to cool down to the room temperature, and finally, stored at 4°C in a refrigerator before use. In order to obtain an enzyme-immobilized biosensor, the ZnONPs-MWCNTs-GCE was dipped into the Cyt c enzyme solution for 20 min. Then, 30 μL (0.6 mg/mL) of Cyt c was subsequently dropped onto the electrode surface for a 30 min incubation time.\(^10\) The electrode was then dried at ambient temperature for 15 min to obtain the proposed biosensor "Cyt c-ZnONPs-MWCNTs-GCE".

### Electrochemical measurements for biosensors

First, 10 mL/0.1 M of a phosphate buffer solution (PBS) with pH 7 was dropped onto an electrochemical cell in which the fabricated electrode was absorbed prior to the electrochemical
determinations. The electrochemical cell was purged with nitrogen gas for 15 min to remove dissolved oxygen. Then, the analyte was added into the cell and stirred at a speed of 1000 rpm. An aliquot of the analyte solutions was introduced into the electrochemical cell, and after the preconcentration time, stirring was stopped. An equilibration period of 10 s was allowed for the solution to become inert. The cyclic voltammetry and differential pulse voltammetry measurements were performed on the fabricated working electrode by scanning the potential towards the positive way, and sweeping was done at an optimized scan rate of 0.01 V s⁻¹ by the DPV method. After each measurement, the working electrode was removed from the system and rinsed with deionized water.

Streptomycin solution
Streptomycin in commercially accessible formulation was admitted in the detection process. Tablet 1 specifies 300 mg of streptomycin per tablet, Tablets 2 and 3 contain 500 mg of streptomycin per tablet were taken for the preparation of pharmaceutical sample. The tablets were crushed with a mortar and pestle, and then the mass of the homogeneous powder was shifted into 25 mL volumetric flask. The powder samples were diluted with PBS (pH 7). The obtained solution was ultra-sonicated for 60 min in order to dissolve it completely and then filtered with Whatman Filter Paper No. 1. An appropriate aliquot amount of the solution was added to the supporting electrolyte in the voltammetric cell and analyzed directly by differential pulse voltammetry.

Instrumentation
Voltammetric measurements of the samples were carried out using a 797 VA analyzer with Computrace software Ver. 1.3.1 from Metrohm (Herisau, Switzerland). A three-electrode system consisting of a platinum wire (acting as a counter electrode), Ag/AgCl (3.0 M KCl and acting as a reference electrode) and a fabricated GCE (acting as a working electrode). The solutions were filtered before the analysis using a 0.45 μM pore size cellulose acetate filter medium and were examined by electrochemistry after the removal of impurities using nitrogen gas for 15 min. Differential Scanning Calorimetry (DSC) and Thermo Gravimetric Analysis (TGA) 1SF Model 1346 with STAR® software Ver. 9.20 (Mettler Toledo, Columbus, OH, USA) instrument were used for the TGA characterization of the bio nanocomposite. The morphologies and characterizations were done with a TEM Model JEM 2100 equipped with a Lab6 emitter, Max Oxford instrument for TEM analysis (JEOL Inc., Peabody USA). Fourier-transform infrared (FT-IR) characterization was performed on a Varian 800 FT-IR scimitar series (by SMM instruments, Durban, RSA). The X-ray diffractions were performed with a Philips PW1710 X-Ray Diffraction Spectrometer (XRD). An ultrasonic bath (Labcon Model 5019 U) was used to prepare nanomaterial suspensions. A CRISON pH meter was used to prepare the buffer solutions. Deionized water was provided by the Aqua MAXTM-basic 360 system.

Results and Discussion
Morphological and structural characterization of Cyt c-ZnONPs-MWCNTs-GCE
A TEM image of ZnONPs is shown in Fig. 2A. these figures confirm the formation of ZnONPs. Based on the Fig. 2A substantiate, the shape of ZnONPs was spherical. From the TEM image, the particle size is predicted to be approximately 7 – 12 nm, which agrees with the XRD data. Figure 2B displays the TEM image of pure MWCNTs and it has tubular-like structure, with the nanotubes having clear inner channels. Figure 2C shows a TEM image of MWCNTs decorated with ZnO nanoparticles. It can be clearly seen that the ZnO nanoparticles are dispersed on the surface of MWCNTs. TGA studies of the ZnONPs, MWCNTs and ZnONPs-MWCNTs were performed from an ambient temperature to 800°C. Figure 2D displays
found to have a hexagonal structure. The particle size of crystallinity of the ZnONPs. The unit cell of the crystal is the peak strength is narrow and sharp, it supports good ZnONPs is also calculated by using the Debye–Scherer formula, observed at 2947 and 2895 cm–1 are due to the symmetric and ethyl alcohol into unstable flammable products. The TGA curves for a usual precursor. At 190°C, the ZnONPs loses a high amount of mass, which may due to the vaporization of water immersed on the surface. The thermograms for pure MWCNTs are revealed with a certain mass loss at 550°C due to the carbon oxidation (red line, Fig. 2D). Furthermore, the ZnONPs-MWCNTs demonstrates negligible weight loss below 100°C that can be attributed to the release of moisture. The produced ZnONPs were examined by the FT-IR method in order to confirm the synthesized ZnONPs. The IR spectrum of synthesized ZnONPs displays peaks at 450, 1070, 1380, 1602 and 3453 cm–1. The sharp peak positioned at 450 cm–1 is attributed to the Zn–O stretching bonds. In addition, the IR peaks at 2348 and 3453 cm–1 indicate the existence of the C =O and –OH moieties. The IR peaks at 63.29°C, the ZnONPs loses the (002), 42.10°C, the (101), 43.44°C, the (200). Moreover, the peak strength is narrow and sharp, it supports good crystallinity of the ZnONPs. The unit cell of the crystal is found to have a hexagonal structure. The particle size of ZnONPs is also calculated by using the Debye–Scherer formula, where 0.89 is Scherer’s constant, d is the average grain size, θ is the Bragg’s diffraction angle, λ is the wavelength of X-rays and β is the full width at half maximum (FWHM) of the diffraction peak corresponding to the plane (101).

Electrochemical characterization of the modified electrode

The electrochemical response of STN at a bare electrode and modified electrodes in 0.1 M PBS at pH 7 was examined by cyclic and differential pulse voltammetry. To observe the electrocatalytic performance of the Cyt c-ZnONPs-MWCNTs-GCE towards the oxidation of STN, Fig. 4A represents the CV responses which were measured at pH 7 PBS in the presence of STN. The anodic peak current intensity was increased, due to an increase in oxidation current density is the adsorption of STN in the solution to the surface of the fabricated GCE followed by conversion of Cyt c (ox) to Cyt c (red) reduced by STN. In addition, STN regenerates Cyt c (red), an intense increase in the anodic current density appears at the potential scanning duration; moreover, the cathodic peak current intensity also increases while the STN is present (Fig. 4A). STN shows anodic and cathodic peaks in the potential window from –0.2 to 0.6 V. Moreover, for all electrochemical assays with STN, the buffer solution was purged with nitrogen gas flow in order to remove any interference of the oxygen reduction reaction. Figure 4A shows cyclic voltammograms of 0.1 mM STN at the bare GCE (curve i), MWCNTs-GCE (curve ii), ZnONPs-MWCNTs-GCE (curve iii) and Cyt c-ZnONPs-MWCNTs-GCE (curve iv) separately. It is worth mentioning that all of the modified electrodes show quasi-reversible redox peaks with various currents. The Cyt c-ZnONPs-MWCNTs-GCE (185 μA) provides a greater electrochemical response than that of GCE (12 μA), MWCNTs-GCE (27 μA) and ZnONPs-MWCNTs-GCE (92 μA), which might be sensibly attributed to the extraordinary electron transfer among the STN and electrode surface. The electrochemical active surface areas of the the bare GCE and Cyt c-ZnONPs-MWCNTs fabricated GCE can be calculated by the Randles–Sevčik equation:

\[ i_{pa} = 2.69 \times 10^{5}AC_{0}D_{r}^{1/2}v^{1/2} \]  

where \( C_{0} \) is the concentration of STN, \( D_{r} \) is the diffusion coefficient, \( A \) is the surface area of the electrode, \( i_{pa} \) is the anodic peak current, \( v \) is the scan rate and \( n \) is the number of electrons transferred. \( D_{r} \) value may be used to estimate the surface area of the modified GCE. The fabricated sensor was found to have a higher surface area of 11.34 mm² compared to that of bare GCE (3.14 mm²). Therefore, Cyt c-ZnONPs-MWCNTs-GCE was selected as the electrochemical biosensor for the studying electrochemical behavior of STN in following experiments.

Influence pH

A performance of the working electrolyte as a biosensor in the determination of STN (0.1 mM) is pH dependent. In the present study, an effect of pH in the range of 3 to 10 on the working electrolyte was examined by cyclic voltammetry and is presented in Fig. 4B. The peak-current intensity increases while increasing the pH values up to 7, and the maximum intensity attains at pH 7. A further increase in the pH value does not increase the performance of working electrolyte, rather, its response decreases gradually. Figure 4C shows the variation of the electric potential with respect to the pH. When the pH is decreased below 6, the potential values become negative, which indicates the participation of the H⁺ ions in the electrode reactions. Therefore, PBS with pH 7 was considered to be the optimal pH and was used for subsequent experiments. The linear-regression equation was found to be \( E_{p} = 0.0963 \mathrm{pH} + 0.483 \) \( (R^2 = 0.9974) \). The resultant slope of the plot in the pH range from 3 to 10 demonstrates that the numbers of electrons and protons are equal in the electrochemical redox reaction of STN, as previously reported.

Deposition time

Due to the adsorptive nature of STN at the electrode surface, cyclic and differential pulse voltammetry methods were selected as a sensitive technique for the detection of STN. The deposition of STN rapidly increases the electrochemical response. The effect of the deposition time on the CV signal of 0.1 mM STN was examined. With increasing deposition time from 30 to 90 s, the peak currents are gradually increased, as shown in Fig. 4D. The peak current reaches its maximum at a deposition time of 90 s, after that peak current starts decreasing due to the saturation of the electrode surface. Therefore, 90 s was chosen as the optimized deposition time for the entire study.
In this investigation, the electrochemical biosensor was modified by covalently attaching Cyt c to the MWCNTs and ZnONPs coated on a glassy carbon electrode surface. The MWCNTs and ZnONPs act as carriers of the electrochemical capture probe to increase the change of the peak currents. In addition to that, Cyt c is used as a redox mediator to generate the electron flow between STN and modified electrode (Scheme 1). A result of the possible scan rate on the electrochemical properties of Cyt c-ZnONPs-MWCNTs-GCE is investigated in 0.1 M PBS (pH 7.0). Initially, the redox peaks of STN increases steadily with increasing scan rates from 0.01 to 0.1 mV s\(^{-1}\) within the potential range of \(-0.2\) to \(0.6\) V. It was observed that there is a linear relationship

**Sensing mechanism and influence of scan rates variation**

In this investigation, the electrochemical biosensor was modified by covalently attaching Cyt c to the MWCNTs and ZnONPs coated on a glassy carbon electrode surface. The MWCNTs and ZnONPs act as carriers of the electrochemical capture probe to increase the change of the peak currents. In addition to that, Cyt c is used as a redox mediator to generate the electron flow between STN and modified electrode (Scheme 1). A result of the possible scan rate on the electrochemical properties of Cyt c-ZnONPs-MWCNTs-GCE is investigated in 0.1 M PBS (pH 7.0) by using the CV (see Fig. 5A). Initially, the redox peaks of STN increases steadily with increasing scan rates from 0.01 to 0.1 mV s\(^{-1}\) within the potential range of \(-0.2\) to \(0.6\) V. It was observed that there is a linear relationship

**Sensing mechanism and influence of scan rates variation**

In this investigation, the electrochemical biosensor was modified by covalently attaching Cyt c to the MWCNTs and ZnONPs coated on a glassy carbon electrode surface. The MWCNTs and ZnONPs act as carriers of the electrochemical capture probe to increase the change of the peak currents. In addition to that, Cyt c is used as a redox mediator to generate the electron flow between STN and modified electrode (Scheme 1). A result of the possible scan rate on the electrochemical properties of Cyt c-ZnONPs-MWCNTs-GCE is investigated in 0.1 M PBS (pH 7.0) by using the CV (see Fig. 5A). Initially, the redox peaks of STN increases steadily with increasing scan rates from 0.01 to 0.1 mV s\(^{-1}\) within the potential range of \(-0.2\) to \(0.6\) V. It was observed that there is a linear relationship
between the peak currents and scan rates. Figure 5B shows the dependence of the anodic and cathodic peaks with respect to the scan rates on the solution of STN. A linear dependency of the redox reaction on the scan rate \(v\) was observed, which demonstrates an adsorption-controlled procedure. In order to confirm this result, a plot between the logarithmic values of peak currents and logarithmic values of scan rates is plotted as shown in Fig. 5C. It provides straight lines with slopes of 1.283 and 1.269 for cathodic and anodic peak currents, individually. The slope values are the same and close to the theoretical value of an ideal adsorption controlled electrochemical reaction (1.12). While increasing the scan rates, the anodic peak potential \(E_{pa}\) moves to the positive direction and the cathodic peak potential \(E_{pc}\) moves to the negative direction. Therefore, the peak to peak separation \(E_p\) was somewhat increased, this behavior demonstrates the quasi-reversible electrochemical process. In order to determine the electrochemical limitations, the difference of the peak potentials with the logarithm of the scan rates at a high scan rate was further plotted according to the Laviron Eq. (4).38

\[
E_{pa} = E^0 - \frac{2.3RT}{\alpha nF} \log v \\
E_{pc} = E^0 - \frac{2.3RT}{(1 - \alpha)nF} \log v
\]

\[
\log k_s = \alpha \log(1 - \alpha) + (1 - \alpha) - \log \left(\frac{RT}{nFv}\right) - \alpha(1 - \alpha)\left(\frac{nF\Delta E_p}{2.3RT}\right)
\]

where \(\alpha\) is the electron transfer coefficient, \(k_s\) is the apparent electron transfer rate constant, \(n\) is the number of electron transfer, \(R\) is the universal gas constant, \(T\) is the temperature and \(E_p\) is the peak to peak separation, i.e. \(E_{pa} - E_{pc}\). The fabrication procedure for the proposed electrochemical biosensor is illustrated in Scheme 1.

**Optimization of incubation time of Cyt c**

In order to optimize the enzyme, the incubation time is one of the most significant parameters. For determining of the STN, it was studied from 5 to 20 min at ambient temperature as shown in Fig. 6. It was initially found that various incubation times of STN produce a visible difference in the peak currents. The results show that the peak current response steadily amplified with extended incubation time and achieved equilibrium at 10 min. After 10 min, the peak currents slowly decreases due to the saturation of the electrode surface. Therefore, 10 min was chosen as the incubation time for the determination of STN.

**Reproducibility and stability of the biosensor**

To investigate the applicability of the proposed electrode, the repeatability of STN detection, stability and reproducibility were studied under the optimized experimental conditions. In order to examine the reproducibility of the electrode preparation process, six modified electrodes constructed on the same fabrication procedure and used for the detection of 0.1 mM STN solution by the DPV technique. From six similar detections, the relative standard deviation (RSD) for the determination of STN was calculated, and found to be 2.86%, which shows a good sensor-to-sensor reproducibility. Furthermore, the repeatability of the anticipated biosensor was examined by detection of 0.1 mM STN and variation coefficient of 3.12% was observed for six successive assays. The peak-current response of the Cyt c-ZnONPs-MWCNTs-GCE was unchanged from its initial value of 96.8% after 10 successive assays (RSD 2.21%). Furthermore, the stability of the modified electrode was investigated by its voltammetric response on the peak current to 0.1 mM STN over 30 days. In the first 15 days, the action of the sensor was engaged about 93% of its original peak current response. Moreover, after 15 days, its response decreased slowly. The Cyt c-ZnONPs-MWCNTs-GCE showed 89% of the initial performance at the end of the 30th day.
This indicates that the proposed electrochemical sensor has good stability over a period of months. Shen and co-workers have reported a photoelectrochemical and electrochemical ratiometric aptasensing for STN. The Cyt-c-ZnONPs-MWCNTs-GCE biosensor showed a low LOD, good stability and satisfactory reproducibility results, compared to the above-mentioned photoelectrochemical and electrochemical ratiometric sensor.

Calibration curve for electrochemical detection of STN

Due to the higher peak current sensitivity and superior peak separation, DPV was used for the sensitive detection of STN using an enzyme immobilized biosensor Cyt-c-ZnONPs-MWCNTs-GCE. The optimal experimental conditions (accumulation potential 0.18 V, accumulation time 60 s, voltage step time 0.38 s, pulse amplitude 0.051 V, scan rate 0.012 V s⁻¹, voltage step 0.21 V, 0.1 M PBS and pH 7) were maintained while performing the experiment. Furthermore, a sequence of DPVs was noted at several concentrations of STN to define its calibration curve. The reaction of the Cyt-c-ZnONPs-MWCNTs-GCE to STN were found to be increased while increasing the concentration of STN. Figure 7 displays DPV curves recorded on the Cyt-c-ZnONPs-MWCNTs-GCE at different STN concentrations in the range of 0.02 to 2.2 μM. Repetitive measurements exposed the possible passivation of the electrode by the products of electrode adsorption or reaction of the STN onto the electrode surface. This results in flowing of the peaks to more positive potentials. The linear regression equation was $I_p = 0.487x + 0.664$ ($R^2 = 0.9904$) with 0.0028 μM of LOD and 0.0562 μM of LOQ at the signal to noise ratio of 3. Therefore, this electrochemical biosensor can be used successfully for the determination of STN in pharmaceutical samples.

Interference studies

The selectivity of Cyt-c-ZnONPs-MWCNTs-GCE for the determination of STN in the mixture of certain inorganic salts and biological substances were studied. The developed biosensor is allowed to enter into the mixer of 0.1 μM STN with the interference substances individually with various concentrations for competing the reactions for 15 min. The differential pulse voltammetry is used to detect the interfering ions in 10 mL of 0.1 mM PBS at pH 7. The concentrations of various interferences and their signal changes are listed in Table 1. Moreover, the tolerance limit was defined as the maximum concentration of interference substances, which can cause an error ±4% in the determination of STN. These effects indicate that the suggested biosensor possesses a good anti-interference capability for the detection of STN.

Analytical application for the proposed sensor

As related to the linear regression equations of bulk form, the developed sensor was successfully utilized for the quantification of STN in tablet dosage forms without any matrix effects. The real sample preparation process is described in the experimental section. For a real sample investigation, an appropriate amount was directly dissolved in deionised water, followed by serial dilution of a 10 mL phosphate buffer solution (pH 7). In addition, recovery studies were employed by the standard addition method, that a known concentrations of pure STN was added to the tablet dosage form. Each sample was tested five times and the detected value was the average of five measurements. The recovery parameters were calculated using the related calibration equations. The recovery was in the range 95 to 105%, and the results are precise and recorded in Table 2. It can be concluded that the found RSD% of recovery values prove that the developed electrochemical biosensor has considerably great potential for the consistency and sensitivity to the detection of STN in pharmaceutical samples.

Local reactivity descriptors of STN

| ε N/eV | ε N–1/eV | X | μ | η | S | W | ΔNmax |
|--------|----------|---|---|---|---|---|-------|
| –5.9881| –2.1214  | 3.8667 | 4.0548 | –4.0548 | 1.9334 | 0.2586 | 4.2519 | 2.0973 |

Understanding of reactive sites on the STN for electrophilic and nucleophilic reactions. For this purpose, the descriptors (local and global reactivity) used to evaluate the reactivity of the molecule, were predicted by DFT calculations at the B3LYP/6-311++G(d,p) level. Fukui functions corresponding to anionic, cationic and neutral radical species of STN were estimated by the following equations.42 We incorporated the hirshfeld charges instead of the Mulliken charges for a better accuracy of the results and these results were compared with the electrostatic potential surface (ESP).42

\[ f_{A}^{\text{nuc}} = \frac{1}{2}[q_{A(N-1)} - q_{A(N+1)}] \]  

\[ f_{A}^{\text{cath}} = \frac{1}{2}[q_{A(N)} - q_{A(N+1)}] \]  

\[ f_{A}^{\text{cath}} = \frac{1}{2}[q_{A(N-1)} - q_{A(N)}] \]  

Where \( f_{A}^{\text{nuc}}, f_{A}^{\text{cath}} \) and \( f_{A}^{\text{cath}} \) are the Fukui functions confirming to the neutral radical, nucleophilic and electrophilic reactions, individually. Mainly, the nucleophiles and electrophiles involve in making interactions with the residues of protein/enzyme. The atomic sites of STN that are prone to the electrophilic/nucleophilic attack are depicted in Table 3. The carbon and oxygen atoms in the aldehyde group that acquire a higher \( f_{A}/f_{K}^{+} \), and are prone to be attacked by the nucleophile. The linkers (C–O) that connect the six and five membered rings are prone to be attacked by the nucleophile. The highest nucleophilicity index acquired by the atoms (C25,C29, N13 and N14) are prone to electrophilic attack. Moreover, the global reactivity descriptors of STN, such as HOMO-LUMO energy gap (\( \epsilon_{\text{H}}-\epsilon_{\text{L}} \)), ionization potential (\( I_{\text{N}} \)), electron affinity (\( A_{\text{N}} \)), electronegativity (\( \chi_{\text{N}} \)), chemical potential (\( \mu_{\text{N}} \)), global hardness (\( \eta_{\text{N}} \)), global softness (\( S_{\text{N}} \)), and global electrophilicity index (\( \omega_{\text{N}} \)) were calculated (Table 4). It shows a very small energy gap of 3.8667 eV. Thus, the molecule STN is more reactive and the atomic sites that are predicted using the Fukui functions are helpful to understand the chemical reactivity of the molecule.

Active binding sites between STN and Cyt c

The proposed sensor shows a significant sensing ability of STN in pharmaceutical substances and in mixers containing inorganic salts, the binding sites between the STN and Cyt c (pdb code: 3NWV) are of future scope to this work. The energy minimization of 10 docked conformations were performed by Lamarckian Genetic Algorithm (LGA) in the Autodock suit of programs. Standard grid dimensions of 60 × 60 × 60 were fixed in order to assemble the ligand and the target in the search space. Figure 8 visualizes the lowest energy docked conformation of STN and Cyt c. The docked conformation illustrates that STN makes strong binding with the residues ASN52, HIS18 and MET80 through hydrogen bonds. The binding energy of the lowest energy conformation is estimated to be 1.87 kcal/mol with the highest torsional energy of 4.77 kcal/mol.
Conclusions

The electrochemical behavior of STN was examined with appropriate techniques. STN was found to be electrochemically energetic in the pH range of 3.0 - 10.0, but the peak currents of STN were higher at pH 7. GCE was fabricated with MWCNTs, which enhanced the response of STN noticeably. Furthermore, the addition of ZnONPs to the MWCNTs to form a nanocomposite electrode, and then immobilizing composite electrode with Cyt c, resulted in the electrochemical biosensor. The higher peak currents, and the response of the STN were appreciably increased and were explained in detail. The fabrication of such electrochemical sensor immobilized with biomolecules can fruitfully be used for analytical applications of STN with simplicity, time saving and reduced costs. The determination of STN was proposed synchronously with varied linear ranges from 0.02 to 2.2 μM, and the LOD, LOQ was obtained to be 0.0028 and 0.0562 μM, respectively (S/N = 5). After the experimental limitations affecting the response sensitivity of the biosensor were optimized, the resulting biosensor not only exhibited high sensitivity and selectivity of STN, but also showed much better reproducibility and repeatability.
