INTRODUCTION

Research on the comorbidity of gambling problems with other psychiatric diagnoses has mainly focused on the comorbidity of gambling and substance-use problems (Bonnaire et al., 2017; Rodriguez-Monguio, Errea, & Volberg, 2017; Wareham & Potenza, 2010), whereas the comorbidity in patients with major psychiatric illness has been less investigated. The first published study on gambling behavior in outpatients with schizophrenia was conducted by Desai and Potenza (2009) and reported a 19% prevalence rate. As far as any psychotic illness, only one study was published on patients with schizophrenia, bipolar illness, depressive psychosis, and schizoaffective disorder, reporting a risk of problem gambling four times higher in patients than the general population (Haydok et al., 2015).

As far as bipolar illness, a mailing survey of the Bipolar Disorder Research Network (Jones et al., 2015) on 750 participants, with a 23% completion rate, found a 10.6% overall rate of problem gambling, whereas severe risk was 2.7%. Another relevant paper is the Epidemiologic Catchment Area study (McIntyre et al., 2007) that found a 13.3% rate of problem gambling in individuals with bipolar disorder.

As for unipolar depressive patients, Kennedy et al. (2010) reported a 9.4% prevalence rate of problem gambling and in another study, Quilty, Watson, Robinson, Toneatto, and Bagby (2011) found a rate of 12.5%. Some authors have also hypothesized a causal relationship in the comorbidity of depression and gambling, by investigating the time course of the two disorders (Chou & Affifi, 2011; Dussault et al., 2016).

Screening for gambling problems in the setting of community mental health (CMH) services may have relevant implications for a population that is generally out of reach from drug addiction services and primary care. It could also help in detecting early stages of gambling addiction and thus give room to implement primary prevention. It is reported that even subjects with low scores on screening tools for gambling do have significant dependence and social harms (Canale, Vieno, & Griffiths, 2016). Furthermore, the high comorbidity in mood disorder patients for gambling and other addictions suggests that the detection of one condition should trigger an assessment and relevant treatment for all comorbid conditions (Kennedy et al., 2010).

ISSN 2062-5871 © 2018 The Author(s)
The study of the comorbidity of gambling within definite psychiatric diagnoses may shed light on the pathophysiology of comorbidities, but mixed diagnostic samples can also be informative on the burden of a complex comorbidity in the setting of psychiatric services. General psychiatric samples are of particular interest, because the well-known social, economic, and legal complications of gambling can be even more distressing in patients with a major psychiatric diagnosis and, as with other addiction disorders, may complicate the course, treatment adherence, and overall prognosis of the main psychiatric illness. To date, only few papers have been published in the general psychiatric population (Aragay et al., 2012; Zimmerman, Chelminski, & Young, 2006).

We conducted a survey on a large psychiatric sample of patients attending two CMH centers in the city of Brescia, Italy, with the aim of estimating the rate of at-risk gambling in the whole sample. We also expected that rates would be different across diagnostic categories and that the associations commonly found in patients with primary gambling or in community surveys would be replicated in patients with severe mental illness.

METHODS

Participants

The study was conducted in the University Psychiatric Unit of the Department of Mental Health of the ASST Spedali Civili of Brescia, Italy. The Psychiatric Unit catchment area is about two thirds of the people living in the city of Brescia and its hinterland, totaling 250,592 inhabitants. It comprises an acute hospital ward, a rehabilitation center, medium long-term facilities, and two CMH centers. The psychiatrists at the CMH regularly visit all the psychiatric unit patients and implement comprehensive treatment plans. Patients with a primary diagnosis of substance use are cared for by separate, dedicated centers, so patients attending the CMH centers have a primary diagnosis of a major psychiatric disorder. The distinction of psychiatric services from services for addictions has been operating in Italy since law 833 passed in 1978. Regions have later gained major responsibility in running the health system and recently, in 2015, Regione Lombardia ruled that psychiatric and addiction services were part of the same mental health department with a single direction. In the city of Brescia, a Service for Behavioral Addictions has been operating for the past 2 years.

All patients attending the CMH centers from January 1 to June 30, 2016 were consecutively included in this study. Inclusion criteria were: (a) age 18–70, (b) IQ > 70, and (c) comprehension of spoken Italian. Patients with a primary diagnosis of organic brain syndrome were excluded from the sample. All subjects were tested by psychiatrists or medical doctors with at least 4 years of clinical experience in psychiatry.

Measures

Basic sociodemographic information was collected using a standard demographic questionnaire. The clinical data collected were personal history of child-adolescent neuropsychiatric disorders, psychiatric comorbidity, alcohol abuse/dependence, substance abuse/dependence, smoking, suicide attempt in the last year and lifetime, and family history of gambling disorder.

All participants completed the 9-item Problem Gambling Severity Index of the Canadian Problem Gambling Index (CPGI; Ferris & Wynne, 2001) and the Mini International Neuropsychiatric Interview (MINI), a brief structured interview for the major axis-I psychiatric disorders in DSM-IV and ICD 10 (Sheehan et al., 1998).

The psychometric properties of the Italian version of CPGI were tested in a large community survey of over 5,000 subjects (Colasante et al., 2013). The internal consistency was elevated (Cronbach’s α = .87) and the confirmatory factor analysis found a single factor with good eigenvalues (4.68). The convergent validity of CPGI was also tested in the comparison with the Lie/Bet Questionnaire showing a highly significant association. Three questions were added that addressed the first game ever played, the main game in the last year, and the preferred place for gambling.

Scores on the CPGI define no-risk gambling (0), low risk (1–2), moderate risk (3–7), and problem gambling (8+). There is evidence from recent literature that an alternative system for scoring the CPGI can yield greater classification accuracy relative to clinician ratings, with the definition of “low to moderate severity problems” (1–4) and “problem gambling” (5+) (Cowlishaw, Gale, Gregory, McCambridge, & Kessler, 2017; Williams & Volberg, 2014). The results are reported according to different cut-off point criteria, while the comparison of prevalence estimates between diagnostic groups and with other studies of the literature is based on the 3+ threshold (Jones et al. 2015; Kennedy et al., 2010; Quilty et al., 2011), defined as “at-risk gambling.”

The interrater reliability of the Italian version of the MINI was tested in 50 psychiatric outpatients (Rossi et al., 2004) and all the kappa values were above 0.73, indicating good agreement. The MINI was supplemented with questions investigating the temporal course of the disorders.

The final decision on a patient diagnosis according to the fourth edition of Diagnostic and Statistical Manual of Mental Disorders (text revision) (American Psychiatric Association, 2000) was made after a joint evaluation of three major sources: the MINI, the treating psychiatrist, and the hospital discharge diagnosis (if present).

Statistical analysis

The analysis of associations with CPGI total score used Student’s t-test with a 0.05 level of significance. All variables associated with gambling in the univariate analysis were entered as independent variables in a linear regression analysis, where the dependent variable was CPGI total score. A stepwise, backward selection was used to remove the least significant variable at each step and in the final model only variables with a significant ($p < .05$) and independent association were left.

Ethics

The study procedure was carried out in accordance with the Declaration of Helsinki. The Institutional Review Board of
the Department of Clinical and Experimental Sciences of the University of Brescia approved the study (NP2884). All subjects were informed about the study and all provided signed informed consent.

RESULTS

Out of 917 patients who were eligible for the study, 17 (1.9%) refused to be interviewed, so that a total of 900 patients were included in the sample. Their mean age was 48.7 years (SD = 13.7). 48.3% were men, 50.2% had only an eighth-grade education or less, 35% were married, and 38% employed. Their main diagnoses were schizophrenia or related disorders (38.3%), unipolar depression (19.8%), bipolar disorder (11.4%), cluster B personality disorder (20.3%), and other disorders (10.2%). In 35.3% of the cases, two or more psychiatric diagnoses were applied. The main sociodemographic and clinical features of our sample are reported in Table 1. The psychotropic drugs most often prescribed were 57.6% antipsychotics, 21.3% mood stabilizers, and 50.0% antidepressants.

At-risk gamblers, as defined by a CPGI score of 3+, were 5.3% (48 subjects; 95% CI: 3.8–6.8). According to different thresholds used by recent literature (0, 1–2, 3–7, 8+ or 0, 1–4, 5+), the following at-risk groups were detected: no risk (0) 90.6% (88.5–92.3), low risk (1–2) 4.1% (3.0–5.6), moderate risk (3–7) 2.0% (1.3–3.1), problem gambling (8+) 3.3% (2.3–4.7) or low to moderate severity problems (1–4) 5.3% (4.0–7.0), and problem gambling (5+) 4.1% (3.0–5.6). Among the subjects who gambled in the last year, 10.1% (7.4–12.8) were at-risk gamblers. The rate of at-risk gambling in the main psychiatric diagnoses was: schizophrenia and related psychosis 4.7% (2.4–7.0), unipolar depression 5.6% (2.2–9.0), bipolar disorder 4.9% (0.7–9.1), and cluster B personality disorder 6.6% (3.0–10.0). The difference between diagnostic groups was not statistically significant.

Table 2 reports the pattern and age at the onset of gambling in the sample studied. Out of the 478 patients who gambled in the last year, 77.6% started to gamble after turning 18 and instant lottery was the most frequent (53.6%) and first game (46.0%) played. Patients mostly gambled in smoke shops (68.6%), with a rate of “sometimes during the year” (56.5%) or “sometimes during a month” (26.2%). The comparison of problem and recreational gamblers showed significant differences in the use of slot machines as the main game (58.4% vs. 10.3%; χ² = 81.8, p < .001) and as the first game (31.2% vs. 10.3%; χ² = 25.1, p < .001). The temporal pattern of comorbidity in those who were problem gamblers showed that 52.1% of cases started to gamble before the beginning of their illness.

The sociodemographic and clinical variables associated with CPGI total score in the sample are reported in Table 3. These were male sex, younger age, a family history of gambling, two or more psychiatric diagnoses, alcohol abuse/dependence, substance abuse/dependence, and tobacco smoking.

All variables with a significant association (p < .05) were entered as independent variables in a linear regression analysis, where the CPGI total score was the dependent variable (Table 4). The variables that independently and significantly predicted CPGI total score were a family history of gambling disorder, two or more psychiatric diagnoses, drug abuse/dependence, and tobacco smoking.

DISCUSSION

To our knowledge, this is the first study to investigate the prevalence of at-risk gambling in a large sample of general psychiatry patients, with estimates on the main diagnostic groups. A comparison of our results to those of other published studies is not easy, since most existing data on the comorbidity of gambling and psychiatric disorders stem from surveys on treatment-seeking gamblers or from community surveys, where common mental disorders like depression and anxiety are the rule. These are definitely different from patients suffering from a major psychiatric disorder attending CMH centers like those included in this study.
In a paper that investigated a large sample of psychiatric outpatients with mixed diagnoses, Zimmerman et al. (2006) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a smaller sample of 100 psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling. In a study that investigated a large sample of psychiatric inpatients with mixed diagnoses (45 mood disorders and 35 psychotic disorders), Aragay et al. (2012) found a 2.3% lifetime and 0.7% current rate of DSM-IV pathological gambling.

Among the studies that collected patients with mood disorders, Quilty et al. (2011) evaluated 275 patients with a high rate of comorbidity and found a 9.4% prevalence rate of problem gambling in major depression and 7.3% in bipolar disorder. The study design of Kennedy et al. (2010) on 579 mood disorder patients was similar to this study and found rates of 12.5% and 12.3% of problem gambling in unipolar depression and bipolar disorder, respectively. However, this study recruited subjects not only in psychiatric outpatient clinics but also through advertising.

The Italian Population Survey on Alcohol and other Drugs (IPSAD; Bastiani et al., 2013) is a cross-sectional survey that included 31,984 subjects on a representative sample of the Italian population with a proportional-stratified randomized sample. A 5.6% rate of at-risk gambling was found in previous year gamblers, while in our sample, the rate was almost double (10.1%). Although a direct comparison with the IPSAD study would need a

| Variable | % (n) |
|----------|------|
| Age at onset of gambling | |
| ≤18 years | 22.4 (107) |

Bergamini et al.

matching of subjects, the difference seems attributable to the presence of high-risk gamblers (CPGI 8+) who were 6.3% in our sample and 1.6% in the community survey. Notably, the national sample included adolescents in the 15–17 age range, who are well known to be at a higher risk of gambling.

The lack of significant differences between our diagnostic subgroups was partly unexpected. We hypothesize that major psychiatric disorders such as schizophrenia, bipolar illness, recurrent unipolar depression, and cluster B personality disorder, with an onset in early adulthood and a severe associated disability can produce a cross-diagnostic vulnerability that acts as a risk factor for gambling.

As far as the temporal pattern of comorbidity, half of our patients with at-risk gambling started to gamble before the beginning of the illness. Previous studies have produced mixed results and interpretations on the causal direction of gambling and psychiatric disorders. In the National Comorbidity Survey Replication (Kessler et al., 2008), pathological gambling followed the onset of psychiatric disorders in three fourths of the cases. In the National Epidemiologic Survey on Alcohol and Related Conditions study on a large community sample, designed with a three-year follow-up, it was found that a baseline diagnosis of problematic gambling predicted new-onset mood episodes, generalized anxiety, and alcohol-use disorder (Chou & Afi fi, 2011). A complex pattern of interaction between gambling and depression was found in an 11-year follow-up study of adolescents (Dussault et al., 2016).

Our finding on the association with slot machines gaming is in line with the findings that slot machine gambling is the most troubling type of game among help-seeking problem gamblers (Castrén et al., 2013). Notably, in the IPSAD survey (Bastiani et al., 2013), slot machines showed the highest association with gambling severity among both one-game players and multigame players (odds ratios equal to 4.3 and 4.5, respectively).

The associations of problem gambling with substance abuse/dependence and tobacco smoking replicate the findings on mental health comorbidity of previous surveys. A meta-analysis on the issue (Lorains, Cowlishaw, & Thomas, 2011) found a high prevalence of comorbid disorders, such as nicotine dependence (60.1%) and substance-use disorder (57.5%), with a wide heterogeneity in estimates across studies for substance-use disorders (26.0%–76.3%).

Some limits of this study must be pointed out. The selection of the CPGI 3/4 cut-off to identify at-risk gambling was criticized (Currie, Hodgins, & Casey, 2013) for collapsing the “moderate” at risk category (score: 3–8) and the “true” problem gambling class (scores of 8+), because the “moderate risk” was not robust in the association with clinical variables. However, Canale et al. (2016) reported in a large community survey in Great Britain that most “low-risk gamblers” (CPGI 1–4) exhibited dependence harms and social harms similar to problem gamblers and found it necessary to consider harms experienced at any level of gambling involvement. In this study, prevalence rates are reported according to different cut-offs, including the 4/5 one.

Our rates could be compared only between diagnostic groups, but we had not a true control group, with the main indirect reference being a large Italian population survey. However, none of the published studies, both on single diagnoses or in mixed groups, had controls without psychiatric disorders, and, when available, the comparison was made with community surveys in the same countries (Haydock, Cowlishaw, Harvey, & Castle, 2015; Jones et al., 2015; Kennedy et al., 2010; Zimmermann et al., 2006).

Another limitation could be the possible co-occurrence of a major psychiatric diagnosis with another, like borderline personality disorder and depression, so that the boundaries between our main diagnostic classes could be more blurred than what was supposed. Anyway, clinicians had to make a choice about what was the primary diagnosis, and some overlapping, like schizophrenia and borderline personality disorder are unlikely. Patients with a diagnosis of schizoaffective disorder were not included to avoid this possible bias.

Finally, data on the cognitive functioning of our patients were not available, although dysfunctions in some cognitive domains, like working memory and inhibition, have been associated with gambling behavior (Potenza et al., 2003; Roca et al., 2008).

CONCLUSIONS

We found a substantial rate of at-risk gambling in a large clinical psychiatry sample, which may be lower than that found in less severe psychiatric morbidity, but definitely higher than that found in the general population. Our data suggest the opportunity to devise a screening routine for gambling in patients attending general psychiatric facilities, in order to detect and treat an unmet need and possibly prevent the personal and social consequences of this comorbidity.

Among future directions, we are planning a follow-up of our patients with at-risk gambling to evaluate the temporal stability of the diagnosis, to identify risk factors for a chronic course of the comorbidity, and its effects on global outcome measures. We are also planning the comparison of our prevalence estimates with those of subjects taken from the large IPSAD community survey, matching for the main sociodemographic variables in order to accurately estimate the risk of belonging to a population with severe mental illness.
