Abstract

A non-gravitational, nonlinear interaction between dark matter and dark energy may result in a future evolution of the Universe which differs from that of the standard ΛCDM model. In particular, the ratio of the energy densities of dark matter and dark energy may approach a stable finite value. For a special case, we find a corresponding analytic solution for the interacting two-component dynamics which is consistent with the supernova type Ia data from the Union2 set. For a broader class of interactions without analytic solutions, a dynamical system analysis classifies stationary points with emphasis on their potential relevance for the coincidence problem. Asymptotically stationary solutions of this kind require a phantom-type ‘bare’ equation of state of the dark energy which, however, does not lead to a big-rip singularity.

1. Introduction

Investigating the properties of the cosmological dark sector has become one of the major activities in physics since the detection of the accelerated expansion of the Universe more than a decade ago [1]. According to the most accepted interpretation, based on Einstein’s general relativity, our Universe is dynamically dominated by two so far unknown components, dark matter (DM) and dark energy (DE). The latter contributes roughly 72% to the total energy budget, the former about 23%. Only about 5% is in the form of conventional, baryonic matter. DE, a substance equipped with a sufficiently large negative pressure, accounts for the accelerated expansion, while DM is needed for successful cosmic structure formation. Alternative and complementary support for this interpretation comes from the anisotropy
The spectrum of the cosmic microwave background radiation [2], from large-scale-structure data [3], from the integrated Sachs–Wolfe effect [4], from baryonic acoustic oscillations [5] and from gravitational lensing [6]. The preferred model is the ΛCDM model which also plays the role of a reference model for alternative approaches to the DE problem. Because of the cosmological constant problem in its different facets and the coincidence problem, i.e. the question of why the ratio of the energy densities of DM and DE is of the order of unity at the present epoch, a host of alternative models has been developed in which the cosmological term is dynamized. Overviews of the situation can be found, e.g., in [7–9]. While in the ΛCDM model and in most of the alternative approaches DM and DE are considered as independent components of the cosmic medium, there exists a line of research that admits a coupling between both dark components. Such coupling does not contradict the overall energy–momentum conservation. Interacting models of this type give rise to a richer dynamics and are particularly useful to address the coincidence problem. Models, applicable to an interaction between DE and DM were introduced by Wetterich [10]. Meanwhile there exists a still growing body of literature on the subject—see, e.g., [11–29] and references therein. A general problem here is the choice of the interaction term. Since neither the physical nature of DE nor the physical nature of DM is known, there does not exist a sound microphysical motivation for a specific interaction either. Therefore, approaches to interacting DE are largely phenomenological, even though it has been argued that being unaware of the possibility of an interaction between both dark components may result in a misled interpretation of observational data [12]. Most of the interactions studied so far are linear in the sense that the interaction term in the individual energy balances of the components is proportional either to the DM density or to the DE density or to a linear combination of both densities (for a recent analysis see, e.g., [13]). Since systems with interactions admit analytical solutions only in special cases, several authors resorted to a dynamical system analysis (see, e.g., [30–32] for the general background) to obtain a qualitative picture of the long-time behavior of the cosmological dynamics [14–20]. Occasionally, nonlinear couplings were studied as well [21, 22]. A product coupling, i.e. an interaction proportional to the product of DM density and DE density was shown to be favored observationally over linear choices in [23]. Also from a physical point of view this type of coupling seems preferred. An interaction between two components should depend on the product of the abundances of the individual components, as, e.g., in chemical reactions. A dynamical system analysis for a specific nonlinear interaction was performed and contrasted with observational results in [24, 25].

It is the purpose of this paper to investigate the long-time behavior for a simple two-component model with a number of nonlinear interactions on the basis of Einstein’s theory. We show that for a particular case there exists an analytic solution with a non-vanishing, positive limit for the ratio of the energy densities of DM and DE. In this case, the equation-of-state (EoS) parameter $w$ of the DE is necessarily of the phantom type, i.e. $w < -1$. Similar stationary points for a larger class of interactions are found with the help of a dynamical system analysis. We classify these points according to their possible relevance for the coincidence problem. The existence of these points requires $w < -1$ as well. However, while non-interacting models with constant $w < -1$ necessarily approach a singularity after a finite time [33, 34], the (nonlinear) interaction quite generally prevents the cosmic evolution from a final big-rip. Moreover, independent of the details of the interaction, a positive total energy density in the critical points necessarily implies an energy transfer from DE to DM. We discuss attractors, stable focuses and centers as potential final states of the cosmic dynamics. The center solution discussed in [25] is recovered as a particular case of our work.

The paper is organized as follows. In section 2, we present the basic relations of the general interacting two-component model. We clarify that the relevant critical points
require a phantom-type EoS parameter and we show that a positive critical density is only compatible with a production of DM at the expense of DE but not with a transfer in the opposite direction. A broad class of nonlinear interactions is introduced in section 3, where we also test a particular analytic solution against supernova type Ia (SNIa) data from the Union2 set [35]. In section 4, we perform a dynamical system analysis. A discussion of how the long-time limit might fit into a viable cosmological scenario is given in section 5. Section 6 summarizes the results of the paper.

2. General analysis

The dynamics of our present Universe is assumed to be dominated by DE and DM. The relevant field equations for the spatially flat, homogeneous and isotropic case then are the Friedmann equation

\[ 3H^2 = 8\pi G (\rho_m + \rho_x), \]  

and

\[ \dot{H} = -4\pi G (\rho_m + \rho_x + p_x). \]  

Here, \( \rho_m \) is the energy density of pressureless DM and \( \rho_x \) is the density of a DE component with a pressure \( p_x \). Throughout this paper we use units with \( c = 1 \). We assume that both components do not conserve separately but interact with each other such that the balance equations take the forms

\[ \dot{\rho}_m + 3H\rho_m = Q \]  

and

\[ \dot{\rho}_x + 3H(1 + w)\rho_x = -Q, \]  

where \( w \equiv \frac{p_x}{\rho_x} \) is the EoS parameter of the DE. The sum of (3) and (4) results in the total energy conservation equation

\[ \dot{\rho} + 3H(\rho + p) = 0, \]  

where the total pressure equals the DE pressure, \( p = p_x \). To address the coincidence problem it is convenient to introduce the ratio \( r \equiv \frac{\rho_m}{\rho_x} \) of the energy densities, which is characterized by the dynamics

\[ \dot{r} = \frac{\rho'_m - \rho'_x}{\rho_m - \rho_x}. \]  

Furthermore, it is also convenient to introduce an effective pressure quantity \( \Pi \) by \( Q = -3H\Pi \) and to replace the derivatives with respect to the cosmic time by derivatives with respect to \( \ln a^3 \), denoted by a prime, i.e. \( \dot{\rho} \equiv \rho'3H \). Then the dynamics of the two-component system is given by

\[ \frac{\rho'_m}{\rho_m} = -1 - \frac{\Pi}{\rho_m}, \quad \frac{\rho'_x}{\rho_x} = -(1 + w) + \frac{\Pi}{\rho_x}, \]

or, alternatively, by

\[ \rho' = -\left(1 + \frac{w}{1 + r}\right)\rho \]

and

\[ r' = r \left[w - \frac{(1 + r)^2}{r\rho} \Pi\right]. \]
All the details of the interaction are encoded in the function $\Pi$. In the interaction-free limit $\Pi = 0$, the stationary point $r_s = 0$ together with $w = -1$ corresponds to the de-Sitter space as the long-time limit of the $\Lambda$CDM model.

The relevant critical points of equation (8) are given by

$$r_c = -1 - w,$$

where the subscript $c$ denotes the critical point. Consequently, for positive values of $r$, the existence of a critical point requires an EoS parameter $w < -1$, i.e. DE of phantom type. This conclusion does not depend on the interaction. A non-zero stationary value for the ratio $r$ can be interpreted as an alleviation of the coincidence problem. The condition $r' = 0$ together with (9) and (10) provides us with

$$\rho_c = -\frac{w}{1 + w} \Pi_c.$$

In general, $\Pi_c = \Pi_c(\rho_c, r_c)$. Therefore, (11) is not an explicit relation for $\rho_c$. Moreover, $\rho_c$ remains undetermined for a linear dependence of $\Pi$ on $\rho$. As shown in section 4 in more detail, this case is degenerate and does not admit a dynamical system analysis. On the other hand, for $\Pi \propto \rho$ equation (9) decouples which will allow us to obtain analytic solutions of the system (8) and (9).

Since $w < -1$, a positive stationary energy density $\rho_c$ in (11) requires $\Pi_c < 0$, equivalent to $Q_c > 0$. Independent of the specific interaction (excluding only a linear dependence $\Pi \propto \rho$), the existence of the critical points $r_c$ and $\rho_c$ requires a transfer from DE to DM. We disregard that as long as $\Pi \propto \rho$ is excluded, the results for the critical points so far do not depend on the structure of $\Pi$. In the following section, we shall consider a specific class of interactions.

3. A class of nonlinear interactions

3.1. Structure of the coupling term

As already mentioned, lacking a microphysically motivated interaction, one has to resort to phenomenological models. Note that the knowledge of a reliable microphysical interaction would be equivalent to already knowing the physical nature of DE. Our principal interest in this paper is nonlinear interactions, i.e. interactions for which the effective pressure $\Pi$ in general is a nonlinear function of the energy densities of the components and/or the total energy density. Motivated by the structure

$$\rho_m = \frac{r}{1 + r} \rho \quad \text{and} \quad \rho_x = \frac{1}{1 + r} \rho,$$

of the components, we consider the ansatz

$$\Pi = -\gamma \rho^m r^s (1 + r)^t = -\gamma \rho^{m+s} \rho_m^s \rho_x^{t-n},$$

where $\gamma$ is a positive coupling constant with a dimension of $\rho^{1-m}$. The powers $m, n$ and $s$ specify the interaction. For fixed values of $m, n$ and $s$ the only free parameter is $\gamma$. A linear dependence of $\Pi$ on $\rho$ corresponds to $m = 1$. While this case is not accessible to a dynamical system analysis (see the comments following equation (11) and section 4 below) it is perfectly admissible in the general dynamics (8) and (9). Moreover, as already mentioned, it is exactly this case which will provide us with analytic solutions of the system (8) and (9).

The effective interaction pressure $\Pi$ is proportional to powers of products of the densities of the components for the special cases $s = -m$, but we shall admit $s$ and $m$ to be arbitrary for the moment. Note that every power of the total energy density $\rho$ in the interaction pressure
with observations, the data leave sufficient room for deviations from either $\xi = 0$. For $s = -m$, the ansatz (13) is equivalent to

$$ Q = 3H \gamma \rho_m^m \rho_m^m = 3H \gamma \rho_m^m r^3. $$

The ansatz (13) contains a large variety of interactions that have been studied in the literature as special cases. This comprises, e.g., the models in [15, 17, 16, 26–29].

As mentioned before, in most of the interacting models in the literature, the interactions $\Pi$ are assumed to be linear in either $\rho_m$ or $\rho_c$. The corresponding source terms are $Q = 3\gamma H \rho_m$ or $Q = 3\gamma H \rho_c$, respectively, or a combination of both (see, e.g., [15, 17, 16, 29]). In our setting, the case $Q = 3\gamma H \rho_m$ is recovered for $(m, n, s) = (1, 1, -1)$, while the combination $(m, n, s) = (1, 0, -1)$ reproduces $Q = 3\gamma H \rho_c$.

In the following subsection, we consider particular combinations of the parameters $(m, n, s)$ which give rise to analytically solvable models with nonlinear interaction terms.

### 3.2. Analytically solvable models

#### 3.2.1. The case $Q = 3H \gamma \frac{\rho_m \rho_c}{\rho_c}$. This example for an analytically solvable nonlinear interaction model, covered by the ansatz (13), follows for $(m, n, s) = (1, 1, -2)$. In such a case, equation (9) reduces to

$$ r = r[w + \gamma], $$

which results in a power-law solution

$$ r = r_0 a^{3(w + \gamma)}. $$

The ratio $r$ decreases for $w + \gamma < 0$. Introducing (16) into (8), we find the energy density

$$ \rho = \rho_0 a^{3(1+w)} \left[ 1 + r_0 a^{3(w+\gamma)} \right]^{1/\gamma}. $$

This case coincides with the interacting model studied in [36–38], relying on an ansatz $r = r_0 a^{-\xi}$ for the energy-density ratio. This ansatz was proposed in [39] in order to address the coincidence problem. The correspondence is $\gamma = -(w + \frac{5}{3})$. For $a \ll 1$, we have $\rho \propto a^{-3}$, for $a \gg 1$ the behavior is $\rho \propto a^{-3(1+w)}$. The $\Lambda$CDM model is recovered for $\xi = 3$ and $w = -1$, equivalent to $\gamma = 0$. The densities of the components are

$$ \rho_m = \rho_{0m} a^{-3(1-\gamma)} \left[ 1 + r_0 a^{3(w+\gamma)} \right]^{-1/\gamma}, $$

and

$$ \rho_c = \rho_{0c} a^{-3(1+w)} \left[ 1 + r_0 a^{3(w+\gamma)} \right]^{-1/(w+\gamma)}, $$

where $\rho_{0m} = \frac{\rho_0}{1+r_0} \rho_0$ and $\rho_{0c} = \frac{1}{1+r_0} \rho_0$, respectively. The non-interacting limit is correctly reproduced for $\gamma = 0$. For $w + \gamma = 0$, the energy-density ratio $r$ is constant and

$$ r = r_0 \Rightarrow \rho = \rho_0 a^{-3(1+\frac{\xi}{3})}. $$

The model based on (17) has been analyzed in some detail in the literature [38, 40, 41]. It represents a testable alternative to the $\Lambda$CDM model. Although the latter is largely consistent with observations, the data leave sufficient room for deviations from either $\xi = 3$ or $w = -1$ which would correspond to a non-vanishing interaction, i.e. $\gamma \neq 0$.  

---

Class. Quantum Grav. 29 (2012) 235001  F Arévalo et al
3.2.2. The case $Q = 3H\gamma \frac{\rho}{\rho'}$. This case corresponds to a choice $(m, n, s) = (1, 2, -2)$. It has the analytic solutions

$$r = r_0 \frac{w}{(w + \gamma r_0)a^{-3w} - \gamma r_0}$$

and

$$\rho = \rho_0 a^{-3(1 - \frac{w}{|w|})} \left[ \frac{(w + \gamma r_0)a^{-3w} + r_0(w - \gamma)}{w(1 + r_0)} \right]^\frac{|w|}{|w| + \gamma}.$$  

(22)

The high-redshift limit of (21) is

$$r \rightarrow \frac{|w|}{\gamma} \quad (a \ll 1).$$

(23)

For $a \ll 1$, i.e. in the past, the ratio $r$ becomes constant. In the opposite limit $a \gg 1$ on the other hand, we find $r \propto a^{-3}$ as in the $\Lambda$CDM case. Assuming $w = -1$, the energy density for small values of the scale factor behaves as

$$\rho \propto a^{-3} \left( 1 + \gamma \right) \quad (a \ll 1).$$

(24)

The interaction constant modifies the typical $a^{-3}$ behavior at high redshifts. In the opposite limit $a \gg 1$, the energy density behaves as $\rho \propto a^{-3(1+w)}$ which coincides with the corresponding dependence of the $w$CDM model. In this case, the interaction does not lead to a different future evolution of the Universe.

3.2.3. The case $Q = 3H\gamma \frac{\rho}{\rho'}$. The third and most interesting analytical solution corresponds to the choice $(m, n, s) = (1, 0, -2)$. For $w < 0$, i.e. $w = -|w|$, the solutions are

$$r = \left( r_0 - \frac{\gamma}{|w|} \right) a^{-3|w|} + \frac{\gamma}{|w|}$$

(25)

and

$$\rho = \rho_0 a^{-3(1 - \frac{|w|^2}{|w| + \gamma})} \left[ \frac{|w| + \gamma + (|w|r_0 - \gamma)a^{-3|w|}}{|w|(1 + r_0)} \right]^{\frac{|w|}{|w| + \gamma}}.$$  

(26)

For $\gamma > 0$, positivity of both $r$ and $\rho$ is guaranteed for $\gamma < |w|r_0$:

$$\gamma < |w|r_0 \quad \Rightarrow \quad r > 0 \quad \text{and} \quad \rho > 0.$$  

(27)

The ratio (25) scales as $r \propto a^{-3|w|}$ for $a \ll 1$. For $w = -1$, this coincides with the scaling of its $\Lambda$CDM counterpart. In the far-future limit, however, we have

$$r \rightarrow \frac{\gamma}{|w|} \quad (a \gg 1),$$

(28)

i.e. the energy-density ratio remains finite, whereas it tends to zero in the $\Lambda$CDM model. The energy density scales as $a^{-3}$ for $a \ll 1$, i.e. we recover an early matter-dominated period. In the limit $a \gg 1$, one has

$$\rho \propto a^{-3\left(1 - \frac{|w|^2}{|w| + \gamma}\right)} \quad (a \gg 1),$$

(29)

which generally does not correspond to a de-Sitter phase.

The solution (26) has the interesting special case $1 - \frac{|w|^2}{|w| + \gamma} = 0$ in which $\rho$ tends to a constant for $a \gg 1$. Under this condition, we have

$$|w|^2 = |w| + \gamma \quad \Rightarrow \quad \gamma = |w|(|w| - 1) \quad \Rightarrow \quad \frac{\gamma}{|w|} = |w| - 1.$$  

(30)
The interaction constant $\gamma$ is directly related to the deviation of $w$ from $w = -1$. Then, the energy density (26) may be written as

$$\rho = \rho_0 \left[ \frac{|w| + |r_0 - (|w| - 1)|a^{-3|w|}}{1 + r_0} \right]^{\frac{1}{3}}. \quad (31)$$

For $r$, we find

$$r = [r_0 - (|w| - 1)]a^{-3|w|} + |w| - 1. \quad (32)$$

The limiting values for $a \gg 1$ are

$$\rho_\infty = \rho_0 \left[ \frac{|w|}{1 + r_0} \right]^{\frac{1}{3}} \quad (33)$$

and

$$r_\infty = |w| - 1. \quad (34)$$

The dynamics results in stationary values for $\rho$ and $r$. Note that $\rho > \rho_\infty$ and $r > r_\infty$. Moreover, the limiting value (34) for $r$ coincides with the stationary value (10). In particular, we have again $w < -1$. To the best of our knowledge, this solution has not been considered before. The role of the interaction in the limiting cases is as follows. In the distant past, e.g. at high redshift, we have $r \gg 1$ and $\rho \approx \rho_\infty$. Then, $\frac{[n]}{r} \approx \frac{[n]}{\rho} \propto r^{-2} \ll 1$, i.e. the interaction is negligible and a matter-dominated phase is correctly reproduced. On the other hand, in the far future, $r \ll 1$ and $\rho \approx \rho_\infty$ are valid. Consequently, $\frac{[n]}{r} \approx \frac{[n]}{\rho} \approx w$ and $\frac{[n]}{\rho} \approx \frac{w}{r}$. In this limit, the interaction is crucial. In other words, the interaction is switched on during the cosmic evolution. In the following, we check whether the solutions (31) and (32) with the final stationary values (33) and (34), respectively, are consistent with current SNIa observations. The crucial quantity is the Hubble rate that corresponds to the energy density (26):

$$H = H_0a^{-\frac{1}{2}(1 - \frac{w^2}{w^2 + 1})} \left[ \frac{|w| + \gamma + (|w|r_0 - \gamma)a^{-3|w|}}{|w|(1 + r_0)} \right]^{\frac{1}{3}} \quad (35)$$

The deceleration parameter changes from $q = \frac{1}{2}$ for $a \ll 1$ to

$$q = \frac{1}{2} \left[ 1 - \frac{3|w|^2}{|w| + \gamma} \right] \quad (a \gg 1). \quad (36)$$

Note that for the case (30) the limiting value is $q = -1$, although $r_\infty > 0$ according to (34), i.e. different from the $\Lambda$CDM model there remains a non-vanishing matter fraction.

For our statistical analysis, we do not specify beforehand to the solutions (31) and (32). Our aim is to clarify whether the parameter combination (30) that corresponds to these solutions has observational support. The free parameters are $|w|$, $\gamma$ and $\Omega_0 = \frac{\rho_0}{\rho_m}$. We performed a Bayesian statistical analysis on the basis of the SNIa data from the Union2 set [35], using the marginalization method for $H_0$ developed in [42]. The result of this analysis is shown in figure 1. The best-fit parameter values are $(\gamma, u, \Omega_0, \chi^2_{\text{min}}) = (0.36_{-0.25}^{+0.60}, -1.20_{-0.26}^{+0.08}, 0.39_{-0.19}^{+0.08}, 540.863)$. These results demonstrate that within the $1\sigma$ region the solutions (31) and (32) with the final stationary values (33) and (34), respectively, are indeed consistent with the observational data. This may indicate a phenomenological solution of the coincidence problem with the help of nonlinear interactions in the dark sector.

For an arbitrary combination of the parameters $m$, $n$ and $s$, analytical solutions of the nonlinear system are hardly available. To get insight into the behavior of the system under more general conditions we shall resort to a dynamical system analysis in the following section.
4. A dynamical system analysis

In this section, we consider the dynamics in the vicinity of the critical points with the help of a dynamical system analysis. This analysis is based on the circumstance that, close to the critical points, the (generally unknown) solution of the nonlinear system behaves as the solution of the system, linearized around the critical points (Hartmann’s theorem and, for purely imaginary eigenvalues, the center manifold theorem (see, e.g., [32] and [20]). Using standard techniques (see, e.g., [31, 32]), the general characteristic equation for the critical points is

\[
\lambda^2 + \left[2 + w - w(1 + w) \frac{\partial_r \Pi}{\Pi} \right] \lambda + (1 + w + w \frac{\partial_\rho \Pi}{\Pi}) = 0.
\]

(37)

Here \(\partial_r \Pi\) and \(\partial_\rho \Pi\) denote the partial derivatives of \(\Pi\) with respect to \(r\) and \(\rho\), respectively. Equation (37) has the solutions

\[
\lambda_{\pm} = \frac{1}{2} \left[ w(1 + w) \frac{\partial_\rho \Pi}{\Pi} - (2 + w) \pm \sqrt{\left(2 + w - w(1 + w) \frac{\partial_\rho \Pi}{\Pi} \right)^2 - 4(1 + w + w \frac{\partial_\rho \Pi}{\Pi})} \right],
\]

(38)
that both the linear interactions and the analytically solvable nonlinear cases of the previous
λ describe an attractor for λ consistent with λ have different signs [32]. For complex eigenvalues λ = α + iβ, it is the sign of α that determines the character of the stationary point. For α = 0, the critical point is a center, for α < 0 it is a stable focus and for α > 0 it is an unstable focus. With the ansatz (13) for the interaction, the eigenvalues (38) are

\[ \lambda_{\pm} = -\frac{1}{2} \left[ (2 + s + (1 + n + s)w) \mp \sqrt{(2 + s + (1 + n + s)w)^2 + 4(m - 1)(1 + w)} \right]. \]  

(39)

Since the analysis is valid only for non-zero eigenvalues, all cases with m = 1, corresponding to a linear dependence of Π on ρ, are not covered by the classification mentioned before. Note that both the linear interactions and the analytically solvable nonlinear cases of the previous section have m = 1. For m = 1, equation (9) is decoupled from ρ and can be solved separately.

For m ≠ 1, the general classification provides us with the following set of critical points.

- Attractor for m > 1 and s < -2\( \frac{1 + n + m}{1 + w} \),
- Unstable for m > 1 and s > -2\( \frac{1 + n + m}{1 + w} \),
- Saddle for m < 1, for all n and s,
- Center for m > 1 and 2 + s + (1 + n + s)w = 0 for n > 1,
- Stable focus for m > 1 and 2 + s + (1 + n + s)w > 0,
- Unstable focus for m > 1 and 2 + s + (1 + n + s)w < 0.

For the critical density, we find (m ≠ 1)

\[ \rho_c = [\gamma |w|^{s+1}(|w| - 1)^{n-1}]^{\frac{1}{2-m}}. \]  

(40)

The corresponding values for the components are

\[ \rho_{mc} = [\gamma |w|^{s+m}(|w| - 1)^{n-m}]^{\frac{1}{2-m}} \]  

(41)

and

\[ \rho_{rc} = [\gamma |w|^{s+m}(|w| - 1)^{n-1}]^{\frac{1}{2-m}}, \]  

(42)

consistent with \( r_c = \rho_{mc} = |w| - 1 \) in (10). Consequently, the fixed points (\( \rho_c, r_c \)) are given by (40) and (10). For m > 1, the critical densities are proportional to a negative power of the interaction constant, i.e. the diverge in the limit \( \gamma \rightarrow 0 \). This limit corresponds to the big-rip singularity of DE models with constant EoS parameters \( w < -1 \) [33, 34]. In other words, any non-vanishing interaction of the type considered here is big-rip avoiding.

In tables 1, 2 and 3 we present potentially interesting examples for different critical points, together with the allowed ranges for the EoS parameters. Figure 2 shows the corresponding phase-space portraits.

For a physical interpretation it is instructive to check the analytic solutions of the linearized system that underlie (38) and (39) explicitly for special cases.

| m | n | s | Π | Q | w |
|---|---|---|---|---|---|
| 0 | -1 | -γρ^{3/2}(1+r)^{-1} | 3\sqrt{\gamma\rho_s} | -1.5 ≤ w < -1 |
| 1 | -3 | -γρ^{3/2}(1+r)^{-3/2} | 3\sqrt{\gamma\rho_s} | -1.125 ≤ w < -1 |
| 2 | -1 | -γρ^{3/2}(1+r)^{-1} | 3\sqrt{\gamma\rho_s} | -1.101 ≤ w < -1 |
| 2 | -3 | -γρ^{3/2}(1+r)^{-3/2} | 3\sqrt{\gamma\rho_s} | -1.0625 ≤ w < -1 |
(i) An attractor with \((m, n, s) = (2, 0, -2)\). This corresponds to \(\Pi = -\gamma \rho^2 (1 + r)^{-2}\). The general expression (40) for the critical density reduces to
\[
\rho_c = \frac{\left| w \right| (|w| - 1)}{\gamma}.
\] (43)

Equation (9) simplifies to
\[
r' = rw + \gamma \rho.
\] (44)

Let us introduce quantities \(f\) and \(g\) which describe small deviations from the critical point:
\[
\rho = \rho_c + f, \quad r = r_c + g.
\] (45)

While in zeroth order \(r, w + \gamma \rho_c = 0\) is valid, we have from (44) and (8), up to a linear order in \(f\) and \(g\),
\[
g' = gw + \gamma f, \quad \text{and} \quad f' = -\frac{g}{\gamma} (|w| - 1).
\] (46)

Eliminating \(f\) yields
\[
g'' + |w|g' + (|w| - 1) g = 0.
\] (47)

This second-order equation with constant coefficients has the solution \(g = g_0 \exp[\lambda x]\), where \(g_0\) is some initial value and \(\lambda\) is determined by \(\lambda^2 + |w|\lambda + (|w| - 1) = 0\), i.e. \(\lambda_{1,2} = -\frac{|w|}{2} \pm \sqrt{\frac{|w|^2}{4} - (|w| - 1)}\). Both solutions are negative and, consistently, represent a special case of (39). Consequently, \(g\) decays exponentially with \(x\). Recalling that \(x = \ln a\), we have
\[
g = g_0 a^{\lambda 1} \quad \text{and} \quad f = \frac{|w| + \lambda}{\gamma} g_0 a^{\lambda 2}.
\] (48)

Since \(\lambda\) is negative, \(g\) and \(f\) decay with a power of the scale factor. It is the scale-factor dependence of (48) that is behind the curves in figure 2(a).
Figure 2. Phase portraits: (a) the interaction $Q = 3yH\rho_m\rho_x$ corresponds to an attractor for $w = -1.08$ and $\gamma = 1$. (b) The same interaction results in a stable focus for $w = -1.2$ and $\gamma = 1$. (c) The interaction $Q = 3yH\rho_m\rho_x$ describes a center with $w = -1.17$ and $\gamma = 1$.

The expression $\frac{w}{1+r}$ in (8) represents the total effective EoS of the cosmic medium. Close to the critical value $\frac{w}{1+r} = -1$ it is given by

$$\frac{w}{1+r} = -1 + \frac{g}{|w|} = -1 + \frac{g|a|^\lambda}{|w|}.$$  \hfill (49)

The deceleration parameter is related to $\frac{w}{1+r}$ by

$$q = -1 - \frac{\dot{H}}{H^2} \Rightarrow q = \frac{1}{2} \left( 1 + 3\frac{w}{1+r} \right).$$  \hfill (50)

In the critical point itself $q_c = -1$ is valid. In the vicinity of the critical point we have

$$q = -1 + \frac{3}{2} \frac{g}{|w|},$$  \hfill (51)

with $g$ from (48). Both the total EoS $\frac{w}{1+r}$ and the deceleration parameter $q$ approach $-1$ with the power $3\lambda$ of the scale factor.

(ii) A similar analysis can be made for the dynamics around a center with $(n, s) = (1, 2)$, corresponding to

$$\Pi = -\gamma \rho^{m-2}\rho_m \rho_x \Leftrightarrow Q = 3H\rho^{m-2}\rho_m \rho_x.$$  \hfill (52)
In this case, the critical density is
\[ \rho_c = \left( \frac{|w|}{\gamma} \right)^{\frac{1}{m-1}}. \] (53)

With the ansatz (45) we have, up to a linear order,
\[ \rho^{n-1} = \rho_c^{n-1} \left[ 1 + (m - 1) \frac{f}{\rho_c} \right]. \] (54)
The linearized system becomes
\[ g' = -\gamma (m - 1)(1 + w) \left( \frac{|w|}{\gamma} \right)^{\frac{m-3}{m-1}} f \quad \text{and} \quad f' = \frac{g}{w} \left( \frac{|w|}{\gamma} \right)^{\frac{1}{m-1}}. \] (55)

This is equivalent to the second-order equation \( f'' - (m - 1)(1 + w)f = 0 \) which, for \( m > 1 \), describes oscillations with a frequency \( \omega = \sqrt{(1 - m)(1 + w)} \), i.e. \( f = f_0 \cos \left( \sqrt{(1 - m)(1 + w)} x \right) \) where \( x = \ln a^2 \). For \( g \) we have an identical equation with solution \( g = g_0 \sin \left( \sqrt{(1 - m)(1 + w)} x \right) \), i.e. the dynamics is described by ellipses in the \( f \)–\( g \) plane. This behavior is visualized in figure 2(c). The change of the total energy density in (8) is given by
\[ \frac{\rho'}{\rho} = f' = -\frac{g}{|w|}. \] (56)

For \( g > 0 \), i.e. if the ratio \( r \) is larger than the critical value, equivalent to an enlarged matter contribution, we have \( \rho' < 0 \), i.e. the total energy density decreases since the effective EqS parameter is larger than \(-1\). On the other hand, for \( g < 0 \), there is an excess of DE and the dynamics is given by \( \rho' > 0 \). The rate of change of \( \rho \) is oscillating about the critical point. The period \( \sqrt{(1 - m)(1 + w)} x = 2\pi \) corresponds to \( a_p = \exp \left[ \frac{2\pi}{\sqrt{(1 - m)(1 + w)}} \right] \).

For \( m = 2 \) and \( w = -1.1 \), e.g., we find \( a_p \approx 750 \) numerically.

In the vicinity of the critical point, we have
\[ q = -1 - \frac{3}{2} \frac{g}{w}. \] (57)

With an oscillatory solution for \( g \) the deceleration parameter oscillates around \( q = -1 \).

This corresponds to an oscillation of the effective total EqS parameter \( \frac{\gamma}{1+w} \) around \(-1\) as well. The cosmic medium as a whole oscillates between phantom- and non-phantom behavior; the phantom divide is crossed periodically.

(iii) A mixed case is the stable focus, e.g., the case \((m, n, s) = (\frac{1}{2}, \frac{1}{2}, -1)\). By a similar analysis we find that the perturbations about the critical point behave as damped oscillations with a frequency (with respect to \( x \)) of \( \frac{1}{2} \sqrt{2(|w| - 1) - (1 + \frac{2}{m})^2} \) and a damping factor \( a^{-\frac{3(1+w)}{2}} \). The critical value \(-1\) for the effective EqS and the deceleration parameter are approached by a corresponding spiralling-in dynamics which is visualized in figure 2(b).

(iv) The case \( m = n = s = 0 \) is an example for a saddle. Here, we have \( \Pi = \text{const} \). Consistent with the corresponding special case of (39), only one of the solutions approaches \( q = -1 \) with a power of the scale factor, the second solution is unstable.

It is interesting to realize that the same interaction may result in different critical points for different ranges of the EqS parameter. The third example in table 1 corresponds to the same expression for \( Q \) as the fourth example in table 2. For the range \(-1.001 \leq w < -1\) the critical point is an attractor, while it is a stable focus for \(-2 \leq w < -1.101\). A similar situation occurs for the second case in table 1 and the third case in table 2.
5. An early matter-dominated phase

The focus in this paper is on the late-time behavior of the cosmological dynamics. However, for this behavior to be part of a viable scenario, the dynamics has to be compatible with the present-time observational data and it has to admit an early matter-dominated phase in order to guarantee structure formation. For the analytic solution (31) and (32) these requirements were satisfied. The situation is less clear for the results of the dynamical system analysis of the last section. To better understand this point, it is useful to write the balances for the components satisfied. The inequality (64) relates the interaction strength to deviations from $\rho_c$. For the analytic solution (31) and (32) these requirements were applicable of the latter inequality also for the analytic solution (31) which has $m = 1$, this condition reduces to $\gamma < 1$, consistent with the result $\gamma \approx 0.36$ of our data analysis. It follows from (58) and (59) that for any value of $\gamma$, considerably smaller than this one, the interaction would only provide a very small correction to the dynamics at the present epoch. On the other hand, $\rho' < 0$ implies

$$\rho'^m + \rho_m[1 - \gamma \rho^m - 1(1 + r)^{s+1}] = 0$$  \hspace{1cm} (58)

and

$$\rho'_c + \rho_c[1 - \gamma \rho^m - 1(1 + r)^{s+1}] = 0.$$  \hspace{1cm} (59)

The inequality (64) relates the interaction strength to deviations from $|w| = 1$ (cf equation (30) for a similar feature of the analytic solutions (31) and (32)). Except for $n = 1$, any $\gamma \rho^m_0 - 1 \ll 1$, equivalent to a small influence of the interaction on the present cosmological dynamics, requires a value $w$ of the EoS parameter close to $w = -1$. In other words, deviations from $w = -1$ are a measure of the interaction strength. At the same time, a small deviation from $w = -1$ corresponds to a small, but non-zero limiting value $r_c < 1$ of the energy-density ratio.
Let us now consider qualitatively the conditions for the existence of an early matter-dominated epoch. According to (8), a matter era with \( \rho \propto a^{-3} \) requires \( |w| \ll 1 \) for \( a \ll 1 \). For a constant value of the EoS parameter \( |w| \) this is achieved for \( r \gg 1 \) at \( a \ll 1 \). Since, according to (10), the far-future limit of \( r \) is smaller than unity (for values of \( w \) slightly but not substantially smaller than \(-1\)), one has \( r' < 0 \) as already mentioned, i.e. a decaying ratio of the energy densities during the cosmic evolution. Assuming accordingly, that at high redshifts \( r \gg 1 \) is valid, the balance equation (58) can be written

\[
\frac{\rho_m'}{\rho_m} \approx -\left[ 1 - \gamma r^{m+n+s-1} \rho_c^{m-1} \right].
\]

Then, under the condition \( r \gg 1 \) and with \( m > 1 \), the interaction term is negligible for \( m + n + s < 1 \) in (65), which corresponds to a matter-dominated phase. By inspection one realizes that this requirement is met by the first, second and fourth cases of table 1 and by the first, second and third cases of table 2. These examples are potential candidates for a scenario which correctly reproduces an early matter-dominated period but predicts a future evolution toward an attractor or a stable focus with a finite, non-vanishing value for the ratio of the energy densities. Also the first, second and fourth examples of table 3 have \( m + n + s < 1 \). For the remaining cases which have \( m + n + s = 1 \) there is no dependence on \( r \), and a matter-dominated phase requires \( \gamma \rho_c^{m-1} \ll 1 \) for \( a \ll 1 \). Although these considerations remain on a heuristic level, preliminary conclusions do not seem to be inconsistent with a scenario that includes standard structure formation.

6. Discussion

Models with an interaction between dark matter (DM) and dark energy (DE) have received considerable attention, since they provide a framework to address the cosmic coincidence problem. We have analyzed here an interacting two-component system of DM and DE with the total energy density \( \rho \) and the ratio of the energy densities of DM and DE \( r = \rho_m/\rho_x \) as independent variables. We have shown that asymptotically finite, positive critical values \( r_c \) and \( \rho_c \) of these variables require a phantom-type EoS for the DE component and an energy transfer from DE to DM, at least in the critical point. These results hold quite generally and do not depend on the details of the interaction. We have investigated in some detail interactions of the type \( Q = 3H\rho^m\rho_x^n\rho_{in}^{m+n+s-1}/\rho_c^{m-1} \) which generalizes a number of models that have been studied so far in the literature. For various combinations of \( m, n \) and \( s \) the resulting dynamics was shown to be asymptotically different from that of the \( \Lambda \)CDM model. As a consequence of the interaction, a phantom-type EoS of the DE does not result in a big-rip singularity. For the particular interaction \( Q = 3H\rho^2/\rho \), we found an analytic solution that reproduces an early matter-dominated phase and approaches a finite, stationary value for the ratio of the energy densities of DM and DE. This solution is consistent with the observational data of SNIa from the Union2 dataset. It implies a direct relation between the interaction strength and deviations from \( w = -1 \). The interaction for this case is negligible at high redshifts but crucially influences the future dynamics.

Based on a dynamical system analysis for a broader class of interactions, we identified attractors, stable focuses and centers as potential limiting configurations of the cosmological dynamics. For attractors and stable focuses (examples are summarized in tables 1 and 2, respectively), the asymptotic value \( q_c = -1 \) of the deceleration parameter is approached by a power of the scale factor. For centers (see the examples in table 3) we find oscillations of the deceleration parameter around this critical point, equivalent to a periodic crossing of the phantom divide for the EoS of the total cosmic substratum. All these models have necessarily
$m > 1$. A qualitative discussion of the conditions under which this class of models admits the existence of an early matter-dominated phase singles out models with $m + n + s < 1$. A more quantitative analysis as well as a study of the perturbation dynamics of nonlinearly interacting models will be the subject of future research.
