Abstract. We explore the effect of cosmic radiative feedback from the sources of reionization on the thermal evolution of the intergalactic medium. We find that different prescriptions for this feedback predict quite different thermal and reionization histories. In spite of this, current data can not discriminate among different reionization scenarios. We find that future observations both from 21-cm and CMB experiments can be used to break the degeneracy among model parameters provided that we will be able to remove the foreground signal at the percent (or better) level.

1. Introduction

It is well known that the temperature increase of the cosmic gas in ionized regions leads to a dramatic suppression of the formation of low-mass galaxies (see Ciardi & Ferrara 2005 for a review). We explore the impact of this effect during cosmic reionization by considering two different feedback prescriptions: (i) suppression model where galaxies can form stars unimpeded provided that their circular velocity is larger than a critical threshold, which is not fixed to a constant value but evolves according to gas temperature (Choudhury & Ferrara 2006); (ii) filtering model, where, depending on the mass of the galaxy, the fraction of gas available to star formation is reduced with respect of the universal value and it is fully specified by the filtering mass at that redshift (Gnedin 2000).

We implement these two different radiative feedback prescriptions into a physically-motivated and observationally tested model of reionization (Choudhury & Ferrara 2005, Choudhury & Ferrara 2006). Although the two feedback prescriptions predicts quite different reionization and thermal histories (see Fig. [1]), in both scenarios it is possible to reproduce a wide range of observational data with a proper choice of few model parameters (the redshift evolution of Lyman-limit absorption...
systems, the Gunn-Peterson and electron scattering optical depths, the cosmic star formation history, and number counts in high-$z$ sources). Thus, we find that existing data are unable to discriminate among the two reionization histories (Schneider et al. 2008). We then explore alternative methods to break these degeneracies using future 21-cm experiment (Schneider et al. 2008) and CMB anisotropy observations (Burigana et al. 2008).

2. 21-cm signal

The spin temperature $T_S$, which represents the excitation temperature of the 21 cm transition, determines whether the signal will appear in emission (if $T_S > T_\gamma$) or in absorption (if $T_S < T_\gamma$). Given the different gas ionization fraction and spin temperature evolution in the range $7 \lesssim z \lesssim 20$, the two models predict different global 21 cm background signals in the observed frequency range $75 \text{ MHz} \lesssim \nu \lesssim 200 \text{ MHz}$. The largest differences in the two models are represented by a ~
15 mK absorption feature in the range 75-100 MHz in filtering model (which is nearly absent in suppression model), and by a global shift of the emission feature preceding reionization towards larger frequencies in the same model, as shown in Fig. 2 (see Schneider et al. 2008 for all details). Since the frequency dependence of the signals and foregrounds are different, the gradient of the brightness fluctuation with frequency might help to discriminate the signal from the relatively smooth foreground in the comparison between the two models, as shown in Fig. 3. Single dish observations with existing or forthcoming low-frequency radio telescopes such as LOFAR, 21CMA, MWA, and SKA can achieve mK sensitivity allowing the identification of these signals provided that foregrounds, which are expected to be three orders of magnitude larger, can be accurately subtracted. The best observational frequencies to discriminate the radiative feedback models through their 21 cm background signal are 73-79 MHz and 82.5-97.2 MHz, where the expected differences in brightness temperatures and gradients are large enough to be detectable with future 21 cm experiments.

3. CMB anisotropies

In this section, we discuss how to discriminate between the two radiative feedback prescriptions (and corresponding reionization histories) with future CMB data (see Burigana et al. 2008 for all details).

By exploiting the ionization and kinetic temperature histories shown in Fig. 1, we compute the Comptonization and the free-free distortion parameters. We find $u \approx 1.69 \times 10^{-7}$, $y_B \approx 9.01 \times 10^{-10}$, and $u \approx 9.65 \times 10^{-8}$, $y_B \approx 5.24 \times 10^{-10}$ respectively for the suppression and the filtering model; these values are clearly well below the COBE/FIRAS limits. The two models show similar ionization and thermal histories at $z \approx 6$ while important differences are predicted at $z \approx 6$. These explain the different spectral distortion levels generated in the two cases. The expected Comptonization distortions are comparable to those that could be in principle observed by a future generation of CMB spectrum experiments.

We then compute the angular power spectrum (APS) of CMB anisotropy including the ionization history in a dedicated Boltzmann code. Our results are reported in Fig. 4. Having neglected for simplicity tensor perturbations, we focus here on the TT (total intensity, i.e. temperature), TE (temperature-polarization cross-correlation), and EE polarization modes of the CMB anisotropy APS. We display also the APS of the foreground in the V band (centered at 61 GHz) of WMAP 3yr data, a frequency where the foreground is found to be minimum (or almost minimum) in both temperature and polarization at the angular scales larger than $\sim 1^\circ$ of relevance in this context.

Fig. 5 shows the relative difference between the EE mode APS of CMB anisotropies for the suppression and filtering models. 

Fig. 4. APS of CMB anisotropies for the three considered modes TT, TE, EE, reported in each panel (solid lines: suppression model; dashes: filtering model). Thick lines denote correlation, while thin lines denote anticorrelation (appearing for the TE mode at $\ell \gtrsim 50$). The APS of the foreground, dominated by the Galactic contribution, is reported for comparison (dot-dashes). See also the text. [Results expressed in terms of thermodynamic temperature fluctuations].

---

Footnotes:
1 The values found for $y_B$ should be considered as lower limits, since it is computed in the diffuse “averaged density” approximation; so, a correction factor $\approx \frac{<n^2>}{<n>^2} > 1$, coming from a proper inclusion of the treatment of density contrast in the intergalactic medium, should be applied.

Fig. 5. Relative difference between the (EE mode) APS of CMB anisotropies for the suppression and filtering models (thick solid lines) is compared with the cosmic and sampling variance limitation (dotted lines) and different foreground residual (dot-dashed lines). See the text for more details.

ported in Fig. 4 compared with the cosmic and sampling variance limitation corresponding to a sky coverage of $\approx 74$ per cent (region between the dotted lines). We report also for comparison the APS from a potential residual foreground (dot-dashes) corresponding to different values of the relative accuracy (at APS level) of the component separation method in the considered range of multipoles: 0.1 (dashed line), 0.03 (dots-dashed line), 0.01 (three dots-dashed line), and 0.003 (long dashes). The difference between the two considered models is significantly larger than the cosmic and sampling variance over a interesting range of multipoles ($\ell \sim 5−15$). The main limitation derives from a possible residual foreground contamination: as evident, a foreground removal accuracy at per cent level (or better) in terms of APS is necessary to accurately exploit the information contained in CMB polarization about the cosmological reionization process. This calls for a further progress in component separation techniques in polarization and for an accurate mapping of the (mainly Galactic) polarized foregrounds in radio and far-IR bands to complement microwave surveys by improving both the foreground physical modeling and the component separation accuracy.

While the difference between the APS of CMB anisotropies in the two models is over-whelmed by (respec. not significantly larger than) the cosmic and sampling variance for the TT (respec. the TE) mode, we find that future accurate large sky coverage observations of EE polarization mode (e.g. from the forthcoming ESA Planck mission or from the next generation of polarization dedicated satellites, as CMBPol and B-Pol) can be used to discriminate between the two reionization histories.

4. Conclusions

We have explored the effect of cosmic radiative feedback from the sources of reionization on the thermal evolution of the intergalactic medium. We implemented two different prescriptions for this feedback into a well-tested, physically-motived model of the early Universe. We found that different prescriptions for this feedback predict quite different thermal and reionization histories. In spite of this differences, current data can not discriminate among different reionization scenarios. Therefore, we explored alternative methods to break this degeneracies using 21-cm experiment and CMB anisotropy observations. We found that future data can distinguish among different reionization histories provided that we would be able to remove the foreground signal at the percent (or better) level.
