Abstract

A detailed analysis of dark matter event rates in minimal supergravity models (MSGM) is given. It is shown analytically that the lightest neutralino \( \tilde{Z}_1 \) is the LSP over almost all of the parameter space, and hence the natural candidate for cold dark matter (CDM). The radiative breaking of \( SU(2) \times U(1) \) constraints are shown to be crucial in determining the expected event rates. Approximate analytic formulae are obtained to determine the gaugino-higgsino content of the \( \tilde{Z}_1 \) particle. From this one can deduce the behavior of the event rates as one varies the SUSY soft breaking parameters and \( \tan \beta \). The constraint on the event rates due to the recently measured \( b \to s + \gamma \) decay is calculated. It is seen that this data eliminates most of the parameter space where \( \mu \) (the Higgs mixing parameter) and \( A_t \) (the t-quark cubic soft breaking parameter) have the same sign. Since the t-quark is close to its Landau pole, \( A_t \) is restricted to be mostly positive, and so most of the \( \mu > 0 \) part of the parameter space is eliminated. However, for \( \mu < 0 \), one finds large regions of parameter space where the event rate is large and exceeds 0.01 events/kg da. The importance of proper treatment of the s-channel Z and Higgs poles in calculating the relic density is stressed.
The implications of the recent new experiments (SMC and E143) on the quark polarizabilities are analysed and it is seen that uncertainties in these generally produce only small uncertainties in the event rates. A discussion is also given of the sensitivity of the expected event rates to changes in the allowed range of $\tilde{Z}_1$ relic density.
1. Introduction

The nature of the dark matter (DM) which makes up more than 90% of the matter of the universe is a particularly important issue as it may have a fundamental impact both on astronomy and particle physics. Dark matter has currently only been detected by its gravitational interactions, and thus may be composed of several constituents, e.g. baryonic dark matter (B), hot dark matter (HDM) and cold dark matter (CDM) (where “hot” and “cold” refer to whether the particle was relativistic or non-relativistic at the time of galaxy formation). One may measure the amount of each species of dark matter by the ratio \( \Omega_i = \rho_i / \rho_c \) where \( \rho_i \) is the mass density of the \( i \)th constituent and \( \rho_c = 3H^2/8\pi G_N \) is the critical mass density (\( H \) is the Hubble constant and \( G_N \) is the Newtonian gravitational constant). Within the framework of the inflationary scenario one has \( \Sigma \Omega_i = 1 \). The amount of baryonic matter is severely limited in the big bang cosmology by the observed abundancies of light elements i.e. \( \Omega_B \lesssim 0.1 \).

Rotation curves of stars imply a density of dark matter in our galaxy of

\[
\rho_{DM} \approx 0.3 \text{GeV/cm}^3
\]

and this matter will be impinging on the Earth with velocity \( v_{DM} \approx 320 \text{ km/s} \). The fact that microlensing find far more machos in the disk than in the halo of the Galaxy implies that at most 30% of the halo dark matter is machos [1]. Thus most of the halo of the Galaxy must be cold dark matter, and it is this dark matter that terrestrial detectors can observe.

A possible source of hot dark matter is massive neutrinos. In this paper we assume that the cold dark matter component is the lightest supersymmetry neutralino, the \( \tilde{Z}_1 \) particle. The anisotropy power spectrum (including the recent COBE data) puts constraints on the relative amounts of HDM and CDM. A reasonable fit to the full spectrum gives \( \Omega_{CDM} : \Omega_{HDM} = 2 : 1 \). Assuming \( \Omega_B \approx 0.1 \) one then estimates \( \Omega_{\tilde{Z}_i} = 0.6 \). What is theoretically calculable is \( \Omega h^2 \) where \( h = (H/100 \text{ km/s Mpc}) \). Current astronomical measurements yield

\[
0.4 \lesssim h \lesssim 0.8
\]

i.e. two groups of measurements of \( h \) exist, one clustering at the lower bound and one at the upper bound. [The inflationary scenario (with zero cosmological constant) requires \( h \approx 0.5 \)]. Thus we estimate

\[
0.1 \leq \Omega_{\tilde{Z}_i} h^2 \leq 0.4
\]

and we will assume these bounds in the following. (Our results are not qualitatively sensitive to the precise upper and lower limits of Eq. (3) and we will
discuss below what changes occur if one perturbs them.) We also note that it has recently been suggested [2] that if the value \( h \approx 0.8 \) is correct, the age of the universe and other cosmological problems could be accounted for by a cosmological constant with \( \Omega \approx 0.6 - 0.8 \), and the remainder being CDM. This would also lead to \( \Omega Z_1 h^2 \) being in the range of Eq. (3).

Current dark matter detectors plan to obtain a sensitivity of \( R \approx 0.1 \) events/kg da. Future developments may improve this to \( R = 0.01 \) events/kg da. We will thus limit our discussion here to the part of the parameter space where

\[
R \gtrsim 0.01 \text{ events/kg da}
\]

since this sensitivity is what one may expect over the next 5-10 years. Detection of the \( \tilde{Z}_1 \) depends on their scattering cross section by quarks in the nuclei of the detector. Thus a calculation of event rates depends on the two things: (i) the relic density of \( \tilde{Z}_1 \) obey the bounds of Eq. (3), which limits the allowed SUSY parameter space, and (ii) a calculation of the \( \tilde{Z}_1 - q \) cross section. We consider these calculations in this paper within the framework of supergravity grand unification models [3]. While this model is not a complete theory it possesses a sufficient number of accomplishments to warrant using it as the dynamical framework. Thus it accounts naturally for grand unification at a scale \( M_G \approx 10^{16} \) GeV implied by the LEP measurements of \( \alpha_1, \alpha_2 \) and \( \alpha_3 \) at \( M_Z \); it allows a natural breaking of supersymmetry (in the hidden sector) at the GUT scale (something that cannot be done in a phenomenologically acceptable way in the MSSM, and is yet to be demonstrated to occur in string theory); it can account for the suppression of FCNC interactions in a natural way; in the minimal model (MSGM) it depends on only four additional parameters and one sign to describe all the masses and interactions of the 32 new SUSY particles. (This may be compared with 110 new parameters that can occur in the MSSM.)

The supergravity interactions of the MSGM produce four supersymmetry soft breaking terms at \( M_G \) scaled by \( m_o \) (universal spin zero mass), \( m_{1/2} \) (universal gaugino mass), and \( A_o \) and \( B_o \) (cubic and quadratic soft breaking constants). One of the remarkable features of this theory is that this spontaneous breaking of supersymmetry at \( M_G \) generates, by radiative renormalization group (RG) corrections, the breaking of SU(2) \( \times U(1) \) at the electroweak scale [4]: supersymmetry breaking produces SU(2) \( \times U(1) \) breaking. We will see below that radiative breaking is a key element in the analysis of dark matter event rates, and failure to include it loses much of the predictive power of the theory.

While the MSGM possesses only four additional parameters to describe
SUSY phenomena, and this is far fewer than the 20 to 30 of the 110 possible new parameters that is commonly assumed in the MSSM, it still possesses a large parameter space. (Ideally, one would like to have four experiments to determine the four parameters, making all further predictions of the theory unique.) Recently, however, there have been two new pieces of data, the CLEO measurement of the $b \rightarrow s + \gamma$ branching ratio [5] and the CDF and DO measurements of the top quark mass [6]. We will see below that while large error flags still remain in these data, they greatly reduce the allowed parameter space.

There has been considerable activity in the recent past to calculate expected event rates for dark matter detectors [7-13]. However, Refs. [7-9] do not impose radiative breaking and thus can get abnormally high event rates (often by choosing the PC odd Higgs to be too light). The major part of the analysis of Ref. [10] is also done in this framework, and when radiative breaking is introduced it is only for the special parameter choice $B_0 = A_o - m_o$, and the entire parameter space is not scanned. Thus Ref. [10] predicts event rates that are too low. The analyses [7-11] also impose relic density constraints which leave out the full thermal averaging over the $Z$ and $h$ (light Higgs) $s$-channel poles. It is known that such omissions can generate serious errors in density calculations [14,15], and we will see below that it is important to treat $s$-channel poles correctly for about half the parameter space. Finally Refs. [7,8] do not include the heavy Higgs, $H$, in the event rate calculation, the importance of which was first pointed out in Ref. [16].

The plan of this paper is the following. In Sec. 2 we briefly review the ideas of radiative electroweak breaking and discuss the origin of the scaling relations between the masses of the light neutralinos and charginos and the gluino. In Sec. 3 we exhibit an approximate analytic formula for the gaugino and higgsino content of the $\tilde{Z}_1$ in the scaling regime. In Sec. 4 we discuss the relic density calculation, exhibit the importance of correct treatment of the $s$-channel resonances, and also discuss the event rate calculations. We also show that uncertainties in the nucleon spin content do not have any significant effect on event rates for all targets except for the lightest ones such as $^3He$ and $CaF_2$. These results are in contrast with a recent analysis [17] where the coherent part of the scattering was ignored and hence claimed a large effect. Sec. 5 is concerned with constraints on event rates and SUSY parameter space due to the $b \rightarrow s + \gamma$ decay and the top quark mass. We show there that there are sizable regions of the parameter space with $R > 0.01$ including this constraint, and thus our results differ from those of Ref.[18] which concludes that with the $b \rightarrow s + \gamma$ constraint, the event rate $R < 0.01$. We discuss in Sec. 6 the effect of varying the endpoints of Eq. (3). Sec. 7 gives the conclusions.
The MSGM predicts that the $\tilde{Z}_1$ is the lightest supersymmetric particle over almost all the parameter space. The analytic analysis of this is given in the Appendix.

2. Radiative Electroweak Breaking

At the GUT scale the MSGM can be described by the superpotential

$$W = \mu_o H_1 H_2 + W_Y + \frac{1}{M_G} W^{(4)}$$

(5)

where $W_Y$ is the cubic Yukawa couplings and $W^{(4)}$ contains any quartic non-renormalizable couplings (which possibly lead to proton decay). The spontaneous breaking of supersymmetry leads to the soft supersymmetry breaking effective potential $V_{SB}$ and gaugino mass term $L_{mass}$,

$$V_{SB} = m_o^2 \Sigma_a z_a^+ z_a + (A_o W_Y + B_o \mu_o H_1 H_2 + h.c)$$

(6)

$$L_{mass} = -m_{1/2} \bar{\lambda}^\alpha \lambda^\alpha$$

(7)

where $\{z_a\}$ are the scalar fields and $\lambda^\alpha$ the gaugino fields. Equations (5-7) arise after the supergravity interactions cause the spontaneous breaking of supersymmetry in the hidden sector, the GUT interactions cause the breaking of the GUT group $G$ to $SU(3) \times SU(2) \times U(1)$, all superheavy and hidden sector fields are integrated out, and non-renormalizable terms scaled by $(1/M_{Pl})$ are neglected. The universality of the soft breaking parameters, $m_o, A_o, B_o$ and $m_{1/2}$, is a consequence of the universality of gravitational couplings, plus the additional assumption that the hidden sector fields in the Kahler potential also couple universally to the physical fields. (This universality also guarantees suppression of FCNC interactions and thus is phenomenologically desirable). The above results are generally insensitive to the nature of the GUT group provided the representations used to break $G$ are not too large (so that GUT threshold corrections are not too big).

The effective potential may be reduced to the electroweak scale by using the renormalization group (RG) equations. Minimizing the Higgs potential with respect to $<H_{1,2}>$ yields [4]

$$\mu^2 = \frac{\mu_1^2 - \mu_2^2 \tan^2 \beta}{\tan^2 \beta - 1} - \frac{1}{2} M_Z^2; \quad \sin 2\beta = \frac{-2B\mu}{2\mu_2^2 + \mu_1^2 + \mu_2^2}$$

(8)

Here $\mu_i^2 = m_{H_i}^2 + \Sigma_i$ where $m_{H_i}^2$ is the running $H_i$ mass at scale $Q \approx M_Z$ and $\Sigma_i$ are loop corrections. The $m_{H_i}^2$ are given by

$$m_{H_i}^2 = m_o^2 + m_{1/2}^2 g(t)$$

(9)
\[ m_{H_2}^2 = m_{1/2}^2 e(t) + A_0 m_{1/2} f(t) + m_0^2 h(t) - k(t) A_0^2 \]  

where the form factors \( e, f, g, h, k \) are defined in Ibañez et al [4], the gluino mass is \( m_{\tilde{g}} = (\alpha_3/\alpha_G) m_{1/2} \) (with \( \alpha_G \) the GUT coupling constant), and \( t = \ln(M^2_G/Q^2) \).

One may show that solutions exist to Eqs. (8), i.e. that SU(2) \( \times \) U(1) is spontaneously broken, if and only if at least one of the supersymmetry soft breaking interactions are non-zero. Thus it is the supergravity interactions at \( M_G \) that give rise to the breaking of SU(2) \( \times \) U(1) at the electroweak scale.

To obtain a qualitative picture of the implications of electroweak breaking, one notes from Eq. (8) that for \( \tan^2 \beta >> 1 \) (i.e. \( \tan \beta \approx 2 - 3 \)) that

\[ \mu^2 \approx -m_{H_2}^2 - \frac{1}{2} M_Z^2 - \Sigma_2 \]  

Thus for electroweak breaking to occur, it is necessary for \( m_{H_2}^2 \) to turn negative. \( \Sigma_2 \) is generally a small correction). The measured value of the top quark mass is \( m_t = (176 \pm 8 \pm 10) \) GeV from CDF [6] and \( m_t = (199^{+19}_{-21} \pm 22) \) GeV from DO [6] while indirect determinations from LEP yield \( m_t = 164^{+9}_{-10} + 6_{-4} \) GeV [19]. These imply that the top is relatively close to its Landau pole. In this domain, for Q at the electroweak scale, \( h(t), e(t) \) and \( f(t) \) are negative and \( g(t) \) and \( k(t) \) are positive. Further, both \( | h | \) and \( | e | \) are O(1). (For a detailed discussion of the effects of the Landau pole see Ref. [20].) Thus \( m_{H_2}^2 \) does indeed turn negative allowing SU(2) \( \times \) U(1) breaking to occur at the electroweak scale.

In the following we will restrict \( m_o \) and \( m_{\tilde{g}} \) to be less than 1 TeV to prevent an unreasonable amount of fine tuning. [Actually we will see that Eq. (4) actually implies \( m_{\tilde{g}} \approx (650-700) \) GeV.]. Eq. (11) then implies

\[ \mu^2 >> M_Z^2 \]  

(12)

(which is satisfied if \( \mu \approx (2 - 3)M_Z \)) for almost the entire parameter space . Note also that the above discussion implies that \( \mu^2 \) is an increasing function of \( m_{\tilde{g}}^2 \) and \( m_o^2 \).

Eq. (12) is essentially the remnants of the gauge hierarchy problem in supersymmetry, i.e. from Eqs. (9-11), \( \mu \) is scaled by \( m_o \) and \( m_{\tilde{g}} \) and we allow the latter to go as high as 1 TeV. It has been previously shown [21] that Eq. (12) leads to a set of scaling relations between the light neutralinos, chargino and gluino,

\[ 2m_{\tilde{Z}_1} \approx m_{\tilde{Z}_2} \approx m_{\tilde{W}_1} \approx \frac{1}{3} - \frac{1}{4} m_{\tilde{g}} \]  

as well as the additional relations

\[ m_{\tilde{Z}_{3,4}} \approx m_{\tilde{W}_2} >> m_{\tilde{Z}_1}; \quad m_H \approx m_{H^\pm} \approx m_A >> m_h. \]  

(14)
Also one finds
\[ 63 \text{GeV} \leq m_h \lesssim 120 \text{GeV} \] (15)
where the lower bound on \( m_h \) is the current LEP limit. Eqs. (12-14) are thus a direct consequence of radiative electroweak breaking, and we will see below that they play a dominant role in determining relic densities and dark matter detection rates.

3. Composition of \( \tilde{Z}_1 \)

The \( \tilde{Z}_1 \) is generally a mixture of gauginos \( \tilde{W}_3, \tilde{B} \) and Higgsinos \( \tilde{H}_1, \tilde{H}_2 \). We write
\[ \tilde{Z}_1 = n_1 \tilde{W}_3 + n_2 \tilde{B} + n_3 \tilde{H}_1 + n_4 \tilde{H}_2 \] (16)
The expansion coefficients \( n_i \) are determined by diagonalizing the neutralino mass matrix. In the \( (\tilde{W}_3, \tilde{B}, \tilde{H}_1, \tilde{H}_2) \) basis this reads [3]
\[ M_{\tilde{Z}} = \begin{pmatrix} \tilde{m}_2 & a & b & c \\ a & \tilde{m}_1 & c & d \\ b & c & o & -\mu \\ d & c & -\mu & o \end{pmatrix} \] (17)
where \( \tilde{m}_i = (\alpha_i/\alpha_3)\tilde{m}_i \), \( a = M_Z \cos \theta_\text{W} \cos \beta \), \( b = -M_Z \cos \theta_\text{W} \sin \beta \), \( c = -M_Z \sin \theta_\text{W} \cos \beta \) and \( d = M_Z \sin \theta_\text{W} \sin \beta \). The \( \tilde{Z}_1 \) is the lowest mass eigenvector of \( M_{\tilde{Z}} \), which may be determined in general numerically. However, as discussed in Sec. 2, radiative breaking implies \( \mu^2 \gg M_Z^2 \). One may generate an approximate analytic form by treating the two blocks proportional to \( M_Z \) perturbatively. To second order perturbation theory one finds

\[ n_1 = -\frac{1}{2} M_Z \frac{1}{\mu} \frac{M_Z}{1 - \tilde{m}_1^2/\mu^2} \sin \theta_\text{W} \sin \beta \left[ 1 + \frac{\tilde{m}_1}{\mu} \right] \] (18)

\[ n_2 = 1 - \frac{1}{2} M_Z^2 \frac{1}{\mu^2} \frac{1}{(1 - \tilde{m}_1^2/\mu^2)^2} \sin \theta_\text{W} \sin \beta \left[ 1 + \frac{\tilde{m}_1}{\mu} \right] \] (19)

\[ n_3 = \frac{M_Z}{\mu} \frac{1}{1 - \tilde{m}_1^2/\mu^2} \sin \theta_\text{W} \sin \beta \left[ 1 + \frac{\tilde{m}_1}{\mu} \right] \] (20)

\[ n_4 = -\frac{M_Z}{\mu} \frac{1}{1 - \tilde{m}_1^2/\mu^2} \sin \theta_\text{W} \cos \beta \left[ 1 + \frac{\tilde{m}_1}{\mu} \right] \] (21)

Eqs. (18-21) differ from the numerical computer results by amounts \( \delta n_i \approx 0.03 \) over almost the entire parameter space (and are generally a good deal better).
Thus one may use them to understand the nature of the solutions. One sees first that the $\tilde{Z}_1$ is mostly bino since $n_2$ deviates from unity by second order effects, $O(M_2^2/\mu^2)$. Usually, $n_2 > 0.95$ and often larger. However, $n_3, n_4$ and $n_1$ are first order, $O(M_Z/\mu)$. This allows the Higgsino components of the $\tilde{Z}_1$ to become considerable e.g. $n_3 \approx 0.2$. The coherent part of the $\tilde{Z}_1$-nucleus scattering in dark matter detectors, depend upon the interference between the gaugino and Higgsino components of the $\tilde{Z}_1$ [7]. Thus such terms can become quite large, and as will be discussed in Sec. 4, this means that the coherent scattering almost always dominates the incoherent (spin dependent) scattering. Thus there is a large difference between a $\tilde{Z}_1$ whose bino amplitude is 0.95 and one which is 100% bino, and one cannot approximate the former as being pure bino. We also note that the above results are a direct consequence of the radiative breaking conditions, and would not in general hold without them.

4. Relic Density and Event Rate Analysis

The primordial $\tilde{Z}_1$, created at the time of the Big Bang, can annihilate in the early universe. The main diagrams for this are shown in Fig. 1 [22]. At high temperature, the $\tilde{Z}_1$ is in thermal equilibrium with its decay products. However, when the annihilation rate falls below the expansion rate of the universe, freeze out occurs at temperature $T_f$. The $\tilde{Z}_1$ are then disconnected from the background and continue to annihilate. In the simplest approximation [23] (accurate to about $\pm$ 25 %) the current relic density is given by

$$\Omega_{\tilde{Z}_1} h^2 \approx 2.5 \times 10^{-11} \left( \frac{T_{\tilde{Z}_1}}{T_\gamma} \right)^3 \left( \frac{T_\gamma}{2.75} \right)^3 \left( \frac{N_f}{J(x_f)} \right)^{1/2}$$

where

$$J(x_f) = \int_0^{x_f} dx \langle \sigma v \rangle; \quad x_f = kT_f/m_{\tilde{Z}_1}$$

(22)

(23)

Here $x = kT/m_{\tilde{Z}_1}$, $N_f$ is the effective number of degrees of freedom at freeze out, $(T_{\tilde{Z}_1}/T_\gamma)^3$ is the reheating factor, and $T_\gamma$ the current microwave radiation temperature (in $^\circ$K). In Eq. (23), $\sigma$ is the annihilation cross section, $v$ is the relative velocity and $\langle >$ means thermal average.

Freeze out generally occurs when the $\tilde{Z}_1$ are non-relativisitic, i.e. at $x_f = kT_f/m_{\tilde{Z}_1} \approx \frac{1}{30}$. Thus the thermal average may be taken over a Boltzmann distribution:

$$\langle \sigma v \rangle = \int_0^\infty dv \sigma v \exp[-v^2/4x]/\int_0^\infty dv \sigma v \exp[-v^2/4x]$$

(24)
The non-relativistic nature of the annihilation process has lead, in the past, to making a non-relativistic expansion of $\sigma v$ i.e. $\sigma v \approx a + b(v^2/c^2) + \cdots$; after which the thermal average becomes trivial to take. This is a good approximation for the t-channel pole diagrams of Fig. 1, and for the s-channel diagrams when $2m_{\tilde{Z}_1}$ is not in the vicinity of the h or Z poles. However, when $2m_{\tilde{Z}_1}$ is near the s-channel poles, the non-relativistic approximation fails [14] and can produce errors as large a factor of 100 [15] due to the fact that $\sigma v$ is a rapidly varying function in this region. Further, the thermal averaging smears the region where this effect can occur (characteristically over a region $\approx 10$ GeV in $m_{\tilde{Z}_1}$ or $\approx 50$ GeV in $m_{\tilde{g}}$). For this situation one can first perform the integral of Eq. (24) analytically, and then calculate Eq. (23) numerically.

In the following, we will investigate the parameter space defined by the following bounds:

$$100\text{GeV} \leq m_o \leq 1\text{TeV}; \quad 150\text{GeV} \leq m_{\tilde{g}} \leq 1\text{TeV}$$

$$-6 \leq A_t/m_o \leq 6; \quad 2 \leq \tan\beta \leq 20$$

The lower bound on $m_{\tilde{g}}$ is the current Tevatron bound and the upper bounds on $m_o$, $m_{\tilde{g}}$ are to prevent excessive fine tuning of parameters. (Similarly, $\tan\beta \gtrsim 30$ represents a fine tuning of the Higgs VEV ratio.) The range on $A_t$ covers the allowed parameter space (when all other experimental constraints are imposed). One may estimate the region of this parameter space where the above discussion of s-channel poles is important. The scaling relations, Eqs. (13,14), allow us to choose $m_{\tilde{g}}$ as the independent variable. One sees from these relations, that, varying over the field parameter space, one is generally near an s-channel resonance (h or Z pole) when $m_{\tilde{g}} \lesssim 450$ GeV, and hence for this region one must treat the s-channel terms accurately. This is borne out by detailed numerical calculations which show that significant errors occur in the calculation of $\Omega_{\tilde{Z}_1}h^2$ with $m_{\tilde{g}} \leq 450$ GeV when the non-relativistic approximation to $<\sigma v>$ is made, while the approximation is generally good for $m_{\tilde{g}} > 450$ GeV. Since the constraint on detection rate, $R \geq 0.01$ events/kg da, requires $m_{\tilde{g}} \lesssim (650-700)$ GeV, we see that a correct treatment of the s-channel poles is important for a large fraction of the total parameter space.

Detection of dark matter impinging on the Earth depends upon the $\tilde{Z}_1$-quark scattering cross section for the quarks in the nuclei of the detector. The basic diagrams are shown in Fig. 2. This process has been studied by a number of authors [24], and can be represented by the following effective Lagrangian:

$$L_{\text{eff}} = (\bar{\chi}_1 \gamma^\mu \gamma^5 \chi_1)[\bar{q}\gamma_\mu(A_qP_L + B_qP_R)q] + (\bar{\chi}_1 \chi_1)(\bar{q}C_qm_qq)$$

10
Here $\chi_1$ is the $\tilde{Z}_1$ field, $q$ is the quark field and $P_{R,L} = (1 \pm \gamma^5)/2$. The coefficients $A_q$ and $B_q$ arise from the $Z$ t-channel pole and the $\tilde{q}$ s-channel pole, while $C_q$ comes from the $h^0$ and $H^0$ t-channel poles and the $\tilde{q}$ s-channel pole. (We follow the notation of Ellis and Flores [7] where explicit formulae for $A_q$, $B_q$, $C_q$ are given for the $\tilde{q}$, $h$ and $Z$ pole diagrams.)

The first term of Eq. (27) gives rise to spin dependent (incoherent) scattering while the second term gives rise to spin independent (coherent) scattering. Summing over all the quarks in the nucleus, the latter term then produces an additional factor of the nuclear mass, $M_N$. The event rate for a detector then takes the form [24]

$$R = [R_{SI} + R_{SD}] \left[ \frac{\rho_{\tilde{Z}_1}}{0.3 GeV/cm^3} \right] \left[ \frac{v_{\tilde{Z}_1}}{320 km/s} \right] \text{events/kg da} \quad (28)$$

where $\rho_{\tilde{Z}_1}$ is the local mass density of $\tilde{Z}_1$, $v_{\tilde{Z}_1}$ the incident $\tilde{Z}_1$ velocity and the spin independent (SI) and spin dependent (SD) rates have the form [25]

$$R_{SI} = \frac{16 m_{\tilde{Z}_1} M_N^2 M_Z^4}{[M_N + m_{\tilde{Z}_1}]^2} | A_{SI} |^2 \quad (29)$$

$$R_{SD} = \frac{16 m_{\tilde{Z}_1} M_N}{[M_N + m_{\tilde{Z}_1}]^2} \lambda^2 J(J+1) | A_{SD} |^2 \quad (30)$$

where $J$ is the nuclear spin and $\lambda$ is defined by $< N | \sum \tilde{S}_i | N > = \lambda < N | \tilde{J} | N >$. We note that for large $M_N$, $R_{SI} \sim M_N$ while $R_{SD} \sim 1/M_N$, showing that the heavy nuclei are best for detectors sensitive to spin independent scattering.

Since the squarks are generally heavy over most of the parameter space, $A_{SI}$ is dominated by its Higgs contributions which has the general form [26]

$$A_{SI}^{Higgs} \sim \frac{g^2}{4 M_W} \left[ \frac{F_h}{m_h^2} \left\{ \frac{\cos \alpha_H}{\sin \beta} \right\} + \frac{F_H}{m_H^2} \left\{ \frac{\sin \alpha_H}{\sin \beta} \right\} \right] u - \text{quark}$$

$$+ \left\{ \frac{\sin \alpha_H}{\cos \beta} \right\} d - \text{quark} \quad (31)$$

where $F_h = (n_1 - n_2 \tan \theta_W)(n_4 \cos \alpha_H + n_3 \sin \alpha_H)$ and $F_H = (n_1 - n_2 \tan \theta_W)(n_4 \sin \alpha_H - n_3 \cos \alpha_H)$ and $\alpha_H$ is the rotation angle needed to diagonalize the $h$-$H^0$ mass matrix. Thus the SI scattering arises from interference between the gaugino and Higgsino parts of the $\tilde{Z}_1$ i.e. from Eqs. (18-21) from the $n_2 \times n_3$ terms of $F_{h,H}$ for most of the parameter space. In general (including the loop corrections to the Higgs mass matrix [27]) one finds that $\tan \alpha_H \approx 0.1$. Hence, for most of the parameter space, the $h$ contribution to $d$-quark scattering is suppressed by a factor of $\tan^2 \alpha_H$ relative to the $H$, and this can overcome the fact that $m_H^2/m_h^2 >> 1$. In fact we find that the $H$ contribution varies
from 1/10 to 10 times the h contribution as one varies over the full parameter space, and it is essential to keep both neutral CP even Higgs bosons in the analysis [16].

In contrast to the above, the contributions to $A_{SD}$ from the Z pole depends on $n_3^n - n_4^n$ which is small by Eqs. (18-21). Thus for heavy nuclei detectors one always has

$$R_{SI} >> R_{SD}$$ (32)

and even for the light CaF$_2$ detector which has a large $\lambda^2 J(J+1)$ value, the spin independent scattering dominates over most of the parameter space.

$R_{SD}$ depends on the spin content of the nucleons defined by

$$< n | \bar{q}\gamma^\mu\gamma^5 q | n > = 2s^\mu_{(n)}\Delta q$$ (33)

where $s^\mu_{(n)}$ is the spin 4-vector of nucleon n, and $\Delta q$ measures the part of the nucleon spin carried by quark q. It has been suggested [17] that the differences between older data [28] and more recent data [29] determinations of $\Delta q$ (particularly $\Delta s$) could produce uncertainties in the value of R leading to errors as large as a factor of 30. This could indeed be the case if the $\tilde{Z}$ was pure gaugino (i.e. $n_2 = 1, n_3 = n_4 = n_1 = 0$) for then $R_{SI}$ would vanish.

However, as we saw above, a significant interference between the gaugino and Higgsino parts of the $\tilde{Z}$ exists (i.e. the $\tilde{Z}$ amplitude has a gaugino amplitude of only about 0.95) leading instead to Eq. (32) for heavy nuclei, minimizing the effect. Fig. 3 shows the ratio between the predicted value of the total R using the new and old data for $\Delta q$ for a Ge detector. The difference is less than 10% over the entire parameter space. While larger errors can exist for a CaF$_2$ detector, where $R_{SD}$ is large, even here the difference is less than ±30% over 92% of the parameter space.

A more serious uncertainty exists in $R_{SI}$ due to a lack of knowledge of the s-quark content of a nucleon defined by $< n | m_s \bar{s}s | n > \equiv f_s M_n$. Estimates of $f_s$ [30] have about a 50% uncertainty leading to a ± (30-50) % uncertainty in $R_{SI}$. This will not, however, change the qualitative nature of the results given below.

One may now understand analytically the dependence of the event rate on the different SUSY parameters. From Eq.(11), we see that $\mu^2$ is an increasing function of $-m_{\tilde{H}_2}^2$ and hence by Eq. (10) an increasing function of $m_{\tilde{g}}$ and $m_o$. As shown in the discussion following Eq. (31), the major contribution to $A_{SI}$ (which dominates the total event rate R) is proportional to $(n_2n_3) [or (n_2n_4)]$ which by Eqs. (18-21) are the leading [O($M_Z/\mu$)] terms. These decrease with increasing $\mu$. Thus one expects R to be a decreasing function of $m_{\tilde{g}}$ and $m_o$. 

12
This indeed was what was seen in the detailed computer calculations of Ref. [12]. Further, for radiative breaking, which implies \( \tan \beta > 1 \), Eq. (31) also shows that the d-quark amplitude is an increasing function of \( \tan \beta \). Again the computer calculations of Ref. [12] show this rapid rise of \( R \) with \( \tan \beta \).

The calculation of the detector event rates now proceeds as follows. One calculates \( \Omega_{Z_{1}h^{2}} \) and selects that part of the parameter space of Eqs. (25,26) that satisfies the constraint of Eq. (3) as well as the LEP and Tevatron bounds on SUSY masses. One then calculates the event rate \( R \) for this allowed part of the parameter space. Figs. 4 and 5 show the maximum and minimum event rates for \( \mu < 0 \) and \( \mu > 0 \) as a function of \( A_t/m_o \) for Ge and CaF\(_2\) detectors as one lets the remaining parameters vary over the allowed parameter space. (The relevant parts of these graphs are for the regions where \( R_{\text{max}} \geq 0.01 \).)

As can be seen from the previous discussion, the largest event rates occur for the largest allowed values of \( \tan \beta \) and for the smallest values of \( m_{\tilde{g}} \). (The sharp peaks and dips in the \( R_{\text{max}} \) curves arise from the fact that a small value of \( m_{\tilde{g}} \) implies by Eq. (13) a small \( m_{\tilde{W}_{1}} \). If this parameter point also satisfies the LEP cut that \( m_{\tilde{W}_{1}} > 45 \text{ GeV} \) it is allowed and gives rise to a large event rate. Otherwise it is excluded.) The Ge detector is generally considerably more sensitive than the CaF\(_2\) detector since its nuclear mass is considerably larger increasing the \( R_{SI} \) contribution [as seen from Eqs. (29, 30)].

Figs. 4 and 5 also show that the parameter space is bounded in \( A_t \) with most of the allowed region occurring for \( A_t > 0 \). This phenomenon is due mainly to the fact that the t quark mass is large and hence close to its Landau pole. As one approaches the Landau pole, the light stop mass, \( m_{\tilde{t}_1} \), obeys [20]

\[
m^2_{\tilde{t}_1} = -\frac{1}{3} \frac{A_R^2}{D_o} + m^2_{\tilde{t}_1}(NP)
\]

where

\[
A_R \cong A_t - 0.613 m_{\tilde{g}}; \quad D_o \cong 0.164[(m^2_{\tilde{t}})^2 - (m_t)^2]/M^2_{W}
\]

\( m^2_{\tilde{t}} \cong 197 \sin \beta \) is the fixed point mass, and \( m^2_{\tilde{t}_1}(NP) \) is a relatively smooth non-pole contribution. For \( A_R^2 \) sufficiently large, the \( \tilde{t}_1 \) becomes tachyonic, eliminating such parameter points from the parameter space. One expects then a lower bound on \( A_t \) for \( A_t < 0 \), and similarly an upper bound for \( A_t > 0 \) (as we are requiring \( m_{\tilde{g}} < 1 \text{ TeV} \)), with the domain of positive \( A_t \) being larger than for the negative \( A_t \) since cancelation in \( A_R \) between the \( A_t \) and \( m_{\tilde{g}} \) term can occur in the former case. One finds, in fact, including correctly the non-pole part in Eq. (34), that for \( m_t \approx 170 \text{ GeV} \)

\[-1.5 \lesssim A_t/m_o \lesssim 5.5\]
Thus the high mass of the $t$ quark eliminates a large amount of the SUSY parameter space.

5. Constraints From $b \to s + \gamma$ Decay

The $b \to s + \gamma$ decay is a sensitive test for new physics, since it is a flavor changing neutral current (FCNC) process. Thus the Standard Model and new physics loops enter at the same order. This is explicitly exhibited in Fig. 6 where the basic diagrams for the decay at scale $\mu \approx M_W$ are given for SUSY models. The $W$-$t$ loop is common with the Standard Model, while the other loops are the additional supersymmetric contributions. The measured CLEO branching ratio for $B \to X_s + \gamma$ is \[ BR(B \to X_s\gamma) = (2.32 \pm 0.5 \pm 0.29 \pm 0.32) \times 10^{-4} \] (37)
or combining all errors in quadrature one has $BR(B\to X_s\gamma) \cong (2.32 \pm 0.66) \times 10^{-4}$. This result represents an additional limitation on the allowed SUSY parameter space, and we discuss in this section the effect the CLEO data has on dark matter detection event rates.

In the spectator approximation, the $B$ meson decay can be related to the $b$ quark decay. It is convenient to define the quantity $R$ as

\[
BR(B \to X_s\gamma) \sim \frac{\Gamma(b \to s + \gamma)}{\Gamma(b \to c + \ell + \bar{\nu}_\ell)} \equiv R \tag{38}
\]

(A CKM and $(m_b)^5$ factor, which have large errors, cancels out in $R$.). Here $BR(B\to X_ce\bar{\nu}_e) = (10.7 \pm 0.5)\%$. The diagrams of Fig. 6 can be described by an effective Hamiltonian \[ H_{\text{eff}} = V_{tb}V_{ts}^* \frac{G_F}{\sqrt{2}} C_7(M_W)Q_7 \] (39)
where $Q_7 = (e/24\pi^2)m_b\bar{s_L}\sigma^{\mu\nu}b_R F_{\mu\nu}$. Here $F_{\mu\nu}$ is the electromagnetic field strength and $m_b$ is the $b$-quark mass. One must use the renormalization group equations to go from scale $\mu = M_W$ to $\mu \simeq m_b$ where the decay occurs. To leading order (LO) in QCD corrections, $R$ is then calculated to be \[ R = |V_{tb}V_{ts}^*|^2 \frac{6\alpha}{\pi I(z)} \left| C_{7}^{eff}(m_b) \right|^2 \] (40)
where $I(z) = 1 - 8z^2 + 8z^6 - z^8 - 24z^4 \ell n z$ is a phase space factor ($z=m_c/m_b$) and
\[ C^\text{eff}(m_t) = \eta^{16} C_7(M_W) + \frac{8}{3} (\eta^{16} - \eta^{16}) C_8(M_W) + C_2(M_W) \]  

(41)

Here \( Q_8 = \left( \frac{g_3}{16\pi^2} \right) m_b s_R \sigma^{\mu\nu} T^A b_L G^A_{\mu\nu} \) where \( T^A \) and \( G^A_{\mu\nu} \) are the gluon generators and field strengths and \( C_2 \) represents operator mixing with the 4-quark operators.

The QCD corrections are large for this process and the next to leading order correction (NLO) are needed to obtain an accurate theoretical prediction. At present, however, not all the NLO terms have been calculated. Thus the theoretical analysis has an estimated error of about \( \pm 30\% \) with a Standard Model (SM) prediction of \( BR[B \rightarrow X_s \gamma] \cong (2.9 \pm 0.8) \times 10^{-4} \) for \( m_t = 174 \) GeV [32]. The \( H^-t \) SUSY diagram of Fig. 6 adds constructively to the SM amplitude while the \( \tilde{W} - \tilde{t} \) loop may enter constructively or destructively with the SM model amplitude. Since the central value of the CLEO data of Eq. (37) already lies about 1 std. below the central value of the SM results, the current data cannot tolerate a large amount of constructive interference with SUSY amplitudes. Thus, in spite of the large errors in the current data, the \( b \rightarrow s + \gamma \) decay produces a significant constraint on the SUSY parameter space.

As seen from Eqs. (14), radiative breaking generally implies \( m_{H^\pm} \) is large, suppressing its contribution to the \( b \rightarrow s + \gamma \) decay. The \( \tilde{t} - \tilde{W} \) diagram can become large, however, when \( m_{\tilde{t}_1} \) and \( m_{\tilde{W}_1} \) are small. The \( \tilde{t} \) (mass)\(^2 \) matrix reads

\[
\begin{pmatrix}
  m_{\tilde{t}_L}^2 & m_t(A_t + \mu c t \beta) \\
  m_t(A_t + \mu c t \beta) & m_{\tilde{t}_R}^2
\end{pmatrix}
\]

(42)

where expressions for \( m_{\tilde{t}_L}^2, m_{\tilde{t}_R}^2 \) are given in [20]. The light \( \tilde{t} \) eigenvalue is

\[
m_{\tilde{t}_1}^2 = \frac{1}{2} (m_{\tilde{t}_L}^2 + m_{\tilde{t}_R}^2) - \left[ \frac{1}{4} (m_{\tilde{t}_L}^2 - m_{\tilde{t}_R}^2)^2 + m_t^2 (A_t + \mu c t \beta)^2 \right]^{1/2}
\]

(43)

Thus \( m_{\tilde{t}_1}^2 \) can become small if \( A_t \) and \( \mu \) can have the same sign and this effect is enhanced due to the fact that \( m_t \) is so large [33]. One expects therefore that when \( A_t \) and \( \mu \) have the same sign the theoretical prediction for \( BR(b \rightarrow s + \gamma) \) will become large if also \( m_{\tilde{W}_1} \) is small, while the SUSY effect on \( BR \ (b \rightarrow s + \gamma) \) will be small for \( A_t \) and \( \mu \) having opposite sign (or \( m_{\tilde{W}_1} \) becoming large). This can be seen explicitly to be the case from detailed computer calculations given in [34].

Eq. (36) shows that the major part of the parameter space has \( A_t > 0 \), and so the \( b \rightarrow s + \gamma \) decay is expected to influence mostly the \( \mu > 0 \) branch.
One may quantify this by requiring that the theoretical rate for \( BR(b \rightarrow s + \gamma) \) be within the 95% CL bounds of the experimental value. One finds then that for \( \mu > 0 \) one is restricted to the region
\[
-1.0 < A_t/m_o < 0.5; \quad \mu > 0
\] (44)
i.e. about 40% of the parameter space of Eq. (36) is eliminated by the \( b \rightarrow s + \gamma \) data! In addition, sections of the parameter space with small \( m_{\tilde{g}} \) are eliminated for \( A_t < 0, \mu < 0 \) and for \( 0 < A_t \leq 0.5, \mu > 0 \).

The effects of the above restrictions are shown in Fig. 7 \((\mu < 0)\) and Fig. 8 \((\mu > 0)\). In Fig. 7 one sees that event rates are reduced in the small domain of \( A_t < 0 \), (as the low \( m_{W_1} \) part of the parameter space is eliminated), but not significantly modified over the remainder of the parameter space where \( A_t > 0 \), since here \( \mu \) and \( A_t \) have opposite signs. Fig. 8 shows that the only remaining part of the parameter space is the narrow band of \( A_t < 0.5 \), and all of the parameter space with \( A_t > 0.5 \) (where \( \mu \) and \( A_t \) have the same sign) is eliminated. Thus the major effect of the \( b \rightarrow s + \gamma \) data is to eliminate regions of parameter space, rather than reduce expected event rates. As can be seen from Figs. 7 and 8, there still remain regions of parameter space with large event rates. (This is to be contrasted with the results stated in [18].)

6. Varying The Bounds On \( \Omega_{\tilde{Z}_1}h^2 \)

The analysis considered above was done within the framework of the bounds of Eq. (3) on \( \Omega_{\tilde{Z}_1}h^2 \). We consider now the effect of varying these bounds. We first note that the \( \tilde{Z}_1 \) annihilation cross section in the early universe arising from the diagrams of Fig. 1 is a decreasing function of \( m_{\tilde{Z}_1} \). Alternately, from the scaling relations Eq. (13), one may say then that \( \Omega_{\tilde{Z}_1}h^2 \) increases as \( m_{\tilde{g}} \) increases. On the other hand, we saw in Sec. 4 that the event rate \( R \) is a decreasing function of \( m_{\tilde{g}} \). We are interested in this paper in the region \( R \geq 0.01 \) events/kg da which will be accessible experimentally in the foreseeable future. This bound on \( R \) then puts an upper bound on \( m_{\tilde{g}} \). The largest allowed value of \( m_{\tilde{g}} \) occurs for the largest value of \( \tan \beta \) and smallest value of \( m_o \), (which by Eqs. (25,26) we are taking as \( \tan \beta \leq 20, m_o \geq 100 \text{ GeV} \)), since \( R \) increases with \( \tan \beta \) and decreases with \( m_o \). One finds then for the parameter space defined by Eqs. (25,26) that for \( \mu < 0 \) one has[35]
\[
m_{\tilde{g}} \lesssim 650 \text{ GeV}; \quad \text{for } R \geq 0.01, \mu < 0
\] (45)
For \( \mu > 0 \), \( m_{\tilde{g}} \) can rise to (700-750) GeV. However, this occurs for \( A_t > 0 \), and as discussed in Sec. 5, this region of the parameter space is eliminated by the
b→ s + γ decay data, and so Eq. (45) represents the true upper bound on m_{˜g} for dark matter that can be detected with current designs of detectors.

A detailed inspection of the full parameter space shows that the limitation R < 0.01 implies then that the early universe annihilation channels ˜Z_1 ˜Z_1 → hh, Zh are closed. The channel ˜Z_1 ˜Z_1 → WW,ZZ is almost always closed, and the small regions in parameter space which allow this annihilation are very close to threshold and hence highly suppressed. Hence, one need not consider the vector meson channels in the analysis of Ω_{ ˜Z_1 h ^2} given in Sec. 4.

The behavior of Ω_{ ˜Z_1 h ^2} and R as a function of m_{ ˜g} also shows that the bound R ≥ 0.01 implies that m_{ ˜g} ≤ 650 GeV. This is exhibited in Fig. 9a. One sees, as shown in Fig. 9b, that Ω_{ ˜Z_1 h ^2} < 0.3 when R ≥ 0.01 at these maximum values of m_{ ˜g}. Thus in this domain, the results obtained above are not sensitive to the precise upper bound in Eq. (3). If one were to lower the upper bound below Ω_{ ˜Z_1 h ^2} = 0.3, then the upper bound on m_{ ˜g} is further reduced. This is shown in Fig. 10, where it is seen that if Ω_{ ˜Z_1 h ^2} < 0.2, then m_{ ˜g} < 400 GeV, which would make the gluino accessible to the proposed high luminosity upgrade of the Tevatron [i.e. the TeV(33)]. We note that in both the inflationary scenario with a cold-hot dark matter mixture or the scenario with cold dark matter and a cosmological constant, low values of Ω_{ ˜Z_1 h ^2} are preferred. This follows from the fact that in the former case one needs a small value of h (i.e. h ≃ 0.5 so that the age of universe be consistent with the estimated age of globular clusters) and in the latter case because Ω_{ ˜Z_1} is small (i.e. Ω_{ ˜Z_1} ≃ 0.2 − 0.4 since the majority of the matter of the universe is in the cosmological constant).

We now turn to the question of sensitivity of results to the lower bound on Ω_{ ˜Z_1 h ^2}. As discussed above, low Ω_{ ˜Z_1 h ^2} arises when m_{ ˜g} is small, which is also the domain of parameter space where R can be large. Also, as discussed in Sec. 4, the peaks and dips of R_{max} in Figs. 4 and 5 arise from whether or not the LEP bound m_{ ˜W_1} > 45 GeV can be satisfied. Figs. 11 and 12 exhibit the effect on the maximum event rates for Pb and CaF_2 detectors when the bound Ω_{ ˜Z_1 h ^2} > 0.10 is raised to Ω_{ ˜Z_1 h ^2} > 0.15. One sees that the sharp peaks get clipped off, but otherwise the results are qualitatively unchanged. There still remains, however, a sizable amount parameter space where R exceeds 0.01.

7. Conclusions

We have examined in this paper the direct detection possibility of ˜Z_1 cold dark matter within the framework of the minimal supergravity model (MSGM) for the parameter space defined by Eqs. (25,26), and for relic densities Ω_{ ˜Z_1 h ^2} in the range given by Eq. (3). [Eq. (3) encompasses the range one would expect from inflationary cosmology for either the cold-hot dark matter senario or the cold dark matter plus cosmological constant possibility.] One further
limits the parameter space so that experimental bounds on SUSY masses are
obeyed. Two new pieces of data, the t quark mass and the $b \to s + \gamma$ branching
ratio, have greatly constrained the SUSY parameter space. Thus the fact that
$m_t$ is large (i.e. close to its quasi infra-red fixed point) limits the domain of $A_t$
to be mostly positive, while the experimental $b \to s + \gamma$ decay rate limits the
parameter space to be mostly where $A_t$ and $\mu$ have the opposite sign. Thus
the majority (though not all) of the allowed parameter space is in the region
where $A_t > 0$ and $\mu < 0$.

Physical quantities in the MSGM depend on four SUSY parameters, $m_o,$ $m_\tilde{g},$ $A_t,$ $\tan \beta,$ and the sign of $\mu$. Thus a general quantity has a complex
behavior as one varies over the full parameter space. Radiative breaking, however, plays a central role in MSGM predictions and allow one to understand analytically the qualitative behavior of the event rate for the detection of $\tilde{Z}_1$ dark matter. Approximate analytic expressions were obtained in Sec. 3 for the content of the $\tilde{Z}_1$ showing that the $\tilde{Z}_1$ was mostly bino, but with a non-
negligible amount of higgsino. One can see from this that the spin independent
(coherent) contribution generally dominates R (and hence the most sensitive
detectors are those with the heaviest nuclei) and that R decreased with $m_o$ and $m_\tilde{g}$ and increases with $\tan \beta$.

Current dark matter detectors hope to obtain a sensitivity of $R > 0.01$ events/kg da in the forseeable future. As seen here, such a sensitivity will al-
low the exploration of a sizable amount of the SUSY parameter space, though
there will still remain large sections that fall below this bound. The domain $R$
$>0.01$ corresponds to $m_\tilde{g} \approx 650$ GeV and is insensitive to the choice of upper
bound on $\Omega_{\tilde{Z}_1} h^2$ of Eq. (3) provided $\Omega_{\tilde{Z}_1} h^2 \approx 0.3,$ and only mildly sensitive to
the lower bound of Eq. (3). Thus dark matter could only be expected to be seen by current detector designs if the gluino is not too heavy.

In N=1 supergravity there are three possible candidates for the LSP. These are the $\tilde{Z}_1$, the $\tilde{\nu}$ and the $\tilde{e}_R$. We discuss here the region of parameter space where the $\tilde{Z}_1$ is the LSP. The basic requirement for this is then that

$$m_{\tilde{e}_R} > m_{\tilde{Z}_1}; \quad m_{\tilde{\nu}} > m_{\tilde{Z}_1}$$ (A.1)

In addition one has the LEP constraint that

$$m_{\tilde{Z}_1} \gtrsim 20\text{GeV}$$ (A.2)

The requirement that the $\tilde{e}_R$ be heavier than $\tilde{Z}_1$ is an experimental constraint as a charged LSP would have already been discovered. We will see that in fact this condition is obeyed for almost the entire parameter space. The region where the $\tilde{\nu}$ is the LSP will also be seen to be very small.

The $\tilde{e}_R$ and $\tilde{\nu}$ masses can be expressed in terms of the basic MSGM parameters as [4]

$$m_{\tilde{e}_R}^2 = m_o^2 + \tilde{\alpha}_G \frac{6}{5} f_1 m_1^2 \frac{1}{2} - \sin^2 \theta_W M_Z^2 \cos 2\beta$$ (A.3)

$$m_{\tilde{\nu}}^2 = m_o^2 + \tilde{\alpha}_G \left[ \frac{3}{2} f_2 + \frac{3}{10} f_1 \right] m_1^2 \frac{1}{2} + \frac{1}{2} M_Z^2 \cos 2\beta$$ (A.4)

where the form factors $f_i(t)$ are defined as

$$f_i(t) = t \left( 2 + \beta_i t \right) / (1 + \beta_i t)^2$$ (A.5)

where $t = 2\ln(M_G/Q)$ and $\beta_i = \tilde{\alpha}_G(\frac{33}{5}, 1, -3)$ are the $U(1)XSU(2)XSU(3)$ $\beta$-functions with $\tilde{\alpha}_G = \alpha_G/4\pi$. In the following we use $\alpha_G = \frac{1}{24}, M_G = 2 \times 10^{16}\text{GeV}, Q = M_Z$. One finds then $f_1 \cong 38.1, f_2 \cong 99.0, f_3 \cong 772.0$. In order to analytically illustrate the results, we will perform the remainder of the calculation in the scaling limit of Eq. (13,14). (A more accurate numerical calculation give results close to the analytic ones.) One can then relate $m_{\frac{1}{2}}$ to the $\tilde{Z}_1$ mass by

$$m_{\tilde{Z}_1} \cong \tilde{m}_1 = (\alpha_1/\alpha_G)m_{\frac{1}{2}}$$ (A.6)

or $m_{\frac{1}{2}} \cong 2.45 m_{\tilde{Z}_1}$. Eqs. (A.3,A.4) then become

$$m_{\tilde{e}_R}^2 \cong m_o^2 + 0.912 m_{\tilde{Z}_1}^2 - \sin^2 \theta_W M_Z^2 \cos 2\beta$$ (A.7)

$$m_{\tilde{\nu}}^2 \cong m_o^2 + 3.19 m_{\tilde{Z}_1}^2 + \frac{1}{2} M_Z^2 \cos 2\beta$$ (A.8)
The requirement that the $\tilde{e}_R$ not be the LSP then becomes an upper bound on $m_{\tilde{Z}_1}$:

$$m_{\tilde{Z}_1} < 11.4 \left[ m_o^2 + \sin^2\theta_W M_Z^2 (-\cos 2\beta) \right]$$  \hspace{1cm} (A.9)

Similarly, the condition that the $\tilde{\nu}$ is heavier than the $\tilde{Z}_1$ becomes a lower bound on $m_{\tilde{Z}_1}$

$$m^2_{\tilde{Z}_1} > 0.456 \left[ -m_o^2 + \frac{1}{2} M_Z^2 (-\cos 2\beta) \right]$$  \hspace{1cm} (A.10)

Eqs. (A.9, A.10, A.2) are three inequalities constraining the parameters $m_{\tilde{Z}_1}$, $m_o$ and $\tan\beta$. In addition we have the fine tuning constraints of $m_o$, $m_{\tilde{g}} < 1$ TeV.

In the scaling limit then Eq. (A.9) implies for $m_{\tilde{g}} = 1$ TeV

$$m_o > 41.9, \text{ for } \tan\beta = 1; \quad m_o \geq 0, \text{ for } \tan\beta \geq 4.7$$  \hspace{1cm} (A.11)

with corresponding smaller lower bounds on $m_o$ for smaller values of $m_{\tilde{g}}$. Thus for almost the entire parameter space the MSGM predicts that the $\tilde{e}_R$ is not the LSP.

Turning to the $\tilde{\nu}$ constraint, we see that the r.h.s. of Eq. (A.10) falls below the LEP bound Eq. (A.2) (and hence becomes irrelevant) when

$$m_o^2 > \frac{1}{2} M_Z^2 (-\cos 2\beta) - (20)^2 / 0.456$$  \hspace{1cm} (A.12)

and hence

$$m_o \geq 0 \text{ for } \tan\beta < 1.24; \quad m_o > 57.3 \text{ GeV for } \tan\beta >> 1$$  \hspace{1cm} (A.13)

Alternately for all $\tan\beta$, Eq.(A.10) is satisfied for all $m_o$ if $m_{\tilde{Z}_1} > 43.6$ GeV (or $m_{\tilde{g}} > 308$ GeV). Thus the $\tilde{\nu}$ is predicted to be heavier than the $\tilde{Z}_1$ for all but a very small portion of the parameter space.

After completion of this paper there has appeared an analysis by H.Baer and M.Brhlick, Florida State University Preprint FSU-HEP-950818, which implements numerically the computation of the relic density without using a power series expansion in velocity near an s-channel resonance. The thermal averaging of this analysis is equivalent to ours.

33. \( m_t^2 \) can also become small if \( m_{t_R}^2 \) turns negative. This in fact is what happens when the t-quark is close to its Landau pole, as discussed in Sec. 4.

34. J. Wu, P. Nath and R. Arnowitt, Phys. Rev. D51, 1371 (1994).

35. We use here value of R for a Pb detector, since this detector is most sensitive as it has the highest mass nuclei.
Figure Captions

Fig. 1 $\tilde{Z}_1$ annihilation diagrams for annihilation in the early universe.

Fig. 2 $\tilde{Z}_1$-quark scattering diagrams for a terrestrial dark matter detector.

Fig. 3 $R(\text{New})/R(\text{Old})$ vs $\mu$ for a Ge detector. “New” data is Ref. [29] and “Old” data Ref. [28].

Fig. 4 Maximum and minimum event rates for Pb (solid) and CaF$_2$ (dashed) detectors as a function of $A_t$ for $\mu < 0$ and $m_t = 168$ GeV. The other parameters are varied over the range of Eqs. (25,26). (From Ref. [12].)

Fig. 5 Same as Fig. 4 for $\mu > 0$.

Fig. 6 Diagrams contribution to $b \to s + \gamma$ decay at W mass scale.

Fig. 7 Maximum and minimum event rates for Pb detector vs $A_t/m_o$ without $b \to s + \gamma$ constraint (solid) and with $b \to s + \gamma$ constraint (dot-dashed) at 95% CL for $\mu < 0$. Other parameters are varied over the range of Eqs. (25,26) with $m_t=168$ GeV. (The minimum event rates are unaffected by the $b \to s + \gamma$ constraint.)

Fig. 8 Same as Fig. 7 for $\mu > 0$. The parameter space with the $b \to s + \gamma$ constraint terminates for $A_t/m_o > 0.5$.

Fig. 9 Maximum value of $m_\tilde{g}$ (Fig. 9a) and maximum value of $\Omega_{\tilde{Z}_1} h^2$ at this $m_\tilde{g}$ (Fig. 9b) as a function of $\tan \beta$ for $\mu < 0$ for domain $R > 0.01$ events/kg da for Pb detector as other parameters are varied over range of Eqs. (25,26) with $m_t = 168$ GeV. The curves from bottom to top are for $A_t/m_o = 0, 2.0, 4.0$.

Fig. 10 Maximum value of $m_\tilde{g}$ as a function of the upper bound on $\Omega_{\tilde{Z}_1} h^2$ for $\mu < 0$ for $\tan \beta = 6, A_t/m_o = 0.5$. (Results are insensitive to the values of $\tan \beta$ and $A_t$.)

Fig. 11 Maximum event rates for Pb detector as a function of $A_t/m_o$ for $\mu < 0$ for $\Omega_{\tilde{Z}_1} h^2 > 0.10$ (solid) and $\Omega_{\tilde{Z}_1} h^2 > 0.15$ (dot-dashed). Other
parameters are varied over the range of Eq. (25,26) with \( m_t = 168 \text{ GeV} \). (The \( b \rightarrow s + \gamma \) decay constraint is not here imposed.)

Fig. 12 Maximum event rates for CaF\(_2\) detector as a function of \( A_t/m_o \) for \( \mu < 0 \) for \( \Omega_{\tilde{Z}_1} h^2 > 0.10 \) (dashed) and \( \Omega_{\tilde{Z}_1} h^2 > 0.15 \) (solid). Other parameters are varied over the range of Eqs. (25,26) with \( m_t = 168 \text{ GeV} \). (The \( b \rightarrow s + \gamma \) decay constraint is not here imposed.)
