(Dated: August 12, 2015)

Exciting temporal oscillations of the density distribution is a high-precision method for probing ultracold trapped atomic gases. Interaction effects in their many-body dynamics are particularly puzzling and counter-intuitive in one spatial dimension (1D) due to enhanced quantum correlations. We consider 1D quantum Bose gas in a parabolic trap at zero temperature and explain, analytically and numerically, how oscillation frequency depends on the number of particles, their repulsion and the trap strength. We identify the frequency with the energy difference between the ground state and a particular excited state. This way we avoided resolving the dynamical evolution of the system, simplifying the problem immensely. We find an excellent quantitative agreement of our results with the data from the Innsbruck experiment [Science 325, 1224 (2009)].

PACS numbers: 03.75.Kk 03.75.Hh, 67.85.-d,

All existing ultracold-gas experiments are carried out with systems which are spatially inhomogeneous due to the presence of an external confining potential [1, 2]. Exciting temporal oscillations of the gas density distribution in such a confined geometry is a basic tool for investigating the spectrum of collective excitations and phase diagram [3–9]. One-dimensional (1D) gases have their own specifics: Enhanced quantum correlations affect their collective excitations spectrum drastically, masking out signatures of the Bose and Fermi statistics of the constituent particles [10, 11]. The exactly solvable homogeneous Lieb-Liniger gas model [12] is a paradigmatic demonstration of that statement. There bosons interact through a δ-function potential of strength \( g_{\text{1D}} > 0 \). Increasing \( g_{\text{1D}} \) suppresses spatial overlap between any two bosons. This leads to a many-body excitation spectrum identical to that of a free Fermi gas in the limiting case of infinite repulsion, \( g_{\text{1D}} = \infty \), known as the Tonks-Girardeau (TG) gas [13]. The presence of an external parabolic potential makes the low-lying part of excitation spectrum to be discrete. The first excited state of the gas, a dipole mode, is interaction independent. It is associated with the center-of-mass oscillations at a trap frequency \( \omega_{z} \). The second excited state is doubly degenerate for \( g_{\text{1D}} = 0 \) and \( g_{\text{1D}} = \infty \). One mode with the interaction-independent frequency \( 2\omega_{z} \) comes from center-of-mass oscillations. Another mode is called the breathing (or compressional) mode. Being excited by a small instantaneous change of the trapping frequency \( \omega_{z} \), this mode has the frequency \( \omega \) which depends on \( g_{\text{1D}} > 0 \), the number of particles \( N \) in the trap, and the gas temperature \( T \).

Experimental investigations of the breathing mode oscillations in 1D ultracold-gas experiments have been reported by several groups [14–16]. It was found that the frequency ratio \( \omega/\omega_{z} \), as a function of the interaction strength, goes through two crossovers: from the value 2 down to \( \sqrt{3} \) and then back to 2 (see, e.g., Fig. 2), as the system goes from non-interacting to weakly interacting, and then from weakly interacting to strongly interacting regime [15]. The latter crossover has been described theoretically for \( N \) going to infinity, by the approach based on the local density approximation (LDA) [17]. A description of the former crossover has been done only numerically for the few particles: \( N \leq 5 \) by using the multilayer multiconfiguration time-dependent Hartree method [18] and \( N \leq 7 \) using numerical diagonalization [19]. Experiments [14, 16] were done in the regime of weak coupling, for which \( \omega/\omega_{z} = \sqrt{3} \) is expected as \( N \) goes to infinity at zero temperature. To what extent are the observed deviations from the value \( \sqrt{3} \) due to finite \( N \) and \( T \) is an open question. Answering it paves a way towards understanding interaction effects in dynamics and thermalization of 1D quantum gases.

In this Rapid Communication we present the analytic and numerical results for the breathing-mode-oscillation frequency \( \omega \) in the repulsive Lieb-Liniger gas in a parabolic trap of frequency \( \omega_{z} \). Using the Hartree approximation we explain how the decrease of \( \omega/\omega_{z} \) from the value 2 down to \( \sqrt{3} \) as the interparticle repulsion increases is linked to a transition from the Gaussian Bose–Einstein condensate (BEC) to the Thomas–Fermi (TF) BEC regime. By further increasing the repulsion strength, \( \omega/\omega_{z} \) goes back to the value 2. This return is associated with the transition from the TF BEC to the Tonks-Girardeau regime and is described within lo-
More specifically, \( \omega \) it possible to get properties [20].

We employ a sum rule approximation, which makes our results for \( \omega \) applicable for arbitrary \( \lambda \). This makes our predictions from the simulations converge to the ones given by Eq. (2) both for arbitrary value of \(-a_{1D}/a_z\). We found that \( \omega \) given by Eq. (2) with \( Q = Q_0 \) misses up to 50% of the deviation from \( 2\omega_z \) value, while with \( Q = Q_e \) it misses 4% at most.

**BEC to TBE crossover.** — We approximate \( \psi_{gs} \) (normalized to \( \langle \psi_{gs}|\psi_{gs} \rangle = 1 \)) with the Hartree variational wave function \( \psi_{gs}^H(z_1, \ldots, z_N) = \prod_{i=1}^N \varphi(z_i) \) for \( N \gg 1 \). This function is found by minimizing the functional \( E[\psi_{gs}^H] = \langle \psi_{gs}^H|H|\psi_{gs}^H \rangle \) with respect to \( \varphi(z) \). The procedure amounts to solving the Hartree eigenvalue equation (same as the Gross-Pitaevskii equation)

\[
\left[ -\frac{1}{2} \frac{\partial^2}{\partial x^2} + \frac{x^2}{2} + \frac{2}{\lambda} |\varphi(x)|^2 \right] \varphi(x) = \epsilon \varphi(x) \tag{3}
\]

for the minimal possible \( \epsilon \). Here \( \varphi(x) = \sqrt{\omega_z} \varphi(z) \), and \( x \) and \( \epsilon \) are dimensionless length and energy given in units of \( a_z \) and \( \hbar \omega_z \), respectively. The Hartree parameter \( \lambda \) reads

\[
\lambda = -\frac{a_{1D}}{N a_z} \tag{4}
\]

The ground-state density distribution found with respect to the Hartree state \( |\psi_{gs}^H \rangle \) is \( n_H(z) = N |\varphi(z)|^2 \) and the average of the operators \( Q_e \) and \( Q_0 \) is \( \langle Q_e \rangle = \langle Q_0 \rangle = \int dz \, z^2 n_H(z) \). Substituting this expression into Eq. (2) and taking into account that \( 2\omega/\omega_z = \lambda/\omega_z \), we find that \( \omega/\omega_z \) depends on \( a_{1D}, a_z, \) and \( N \) through a single parameter \( \lambda \) within the Hartree approximation.

We explore the dependence of \( \omega/\omega_z \) on \( \lambda \). Deep in the Gaussian BEC regime, \( \lambda \gg 1 \), we use a series expansion in the harmonic oscillator wave functions for \( \varphi(z) \) and solve Eq. (3) perturbatively. We get

\[
\omega^2/\omega_z^2 \simeq 4 \left( 1 - \epsilon \lambda^{-1} \right), \quad \lambda \to \infty, \tag{5}
\]

where \( \epsilon = 1/\sqrt{8\pi} \). Perturbation theory for the many-body wave functions of Hamiltonian (1) extends the validity range of Eq. (5) to arbitrary \( N \geq 2 \). Note that the Hartree approximation is only valid in the large \( N \) limit. Indeed, Eq. (3) in which \( \lambda \) is replaced with \( \lambda_N = -a_{1D}/[(N - 1) a_z] \) minimizes the energy functional for any \( N \geq 2 \). This implies \( \langle Q_0 \rangle = N \langle Q_e \rangle / (N - 1) = \int dz \, z^2 n_H(z) \). Being substituted into Eq. (2) both \( \langle Q_0 \rangle \) and \( \langle Q_e \rangle \) lead to Eq. (5) with \( \lambda \) replaced by \( \lambda_N \), that is, to the result which is correct in the large \( N \) limit only. Note also that the ground-state wave function of
Hamiltonian (1) obtained with perturbation theory and used for the sum rule (2) with $Q = Q_c$ gives Eq. (5) correctly. This supports our approach to DMC simulations (detailed later in the Rapid Communication), in which we rely on Eq. (2) and $Q = Q_c$.

In the case $\lambda \ll 1$ Eq. (3) results in an inverted parabola density profile, characteristic of the TF BEC regime

$$n_H(z) = N \frac{(\theta z)^{\frac{3}{2}}}{4a_z} \left(1 - \frac{z^2}{Z^2}\right) \theta \left(1 - \frac{z^2}{Z^2}\right), \quad \lambda \to 0.$$  

(6)

Here $\theta$ is the Heaviside step function, and $Z/a_z = (3/\lambda)^{1/3}$. Substituting Eq. (6) into Eq. (2) we get $\omega/\omega_z = \sqrt{3}$.

In the case of arbitrary $\lambda$ we solve Eq. (3) numerically. The plot of $\omega^2/\omega_z^2$ as a function of $\lambda$ is shown in Fig. 2. We observe a smooth crossover between the $\lambda \ll 1$ (TF BEC) and $\lambda \gg 1$ (Gaussian BEC) regimes. We find that $\omega^2/\omega_z^2 \approx 3.5$ at $\lambda = 1$, defined as a reference point separating these regimes (see Fig. 1).

**TF BEC to TG crossover.** — This crossover is associated to an interplay of the parameters $\lambda$ and $N^{-3/2}$; see Fig. 1. It may not be captured within the Hartree approximation, which does not contain $N^{-3/2}$ as a parameter independent of $\lambda$. Instead, we may use LDA [17]. It is only valid in the large $N$ limit, and is based on the assumption that the local chemical potential at a point $z$ is equal to the chemical potential in a homogeneous system that has the same density $n(z)$. Therefore $\mu_{loc}(n(z)) = V(Z) - V(0)$ for $|z| \leq Z$ and vanishes for $|z| > Z$ in model (1). Here $Z$ is the Thomas-Fermi radius of the gas cloud, whose value is set by the normalization condition $\int_{-Z}^{Z} dz n(\mu_{loc}(z)) = N$. The dependence of $\mu_{loc}$ on $n$ in the homogeneous Lieb-Liniger model (Eq. (1) with $V = 0$) was found in Ref. [12]. Using Eq. (2) with $\langle Q_c \rangle = \langle Q_0 \rangle = \int dz z^2 n(z)$ we get $\omega/\omega_z$ readily. The result depends on $a_{1D}, a_z$, and $N$ through a single parameter $\Lambda = N a_{1D}^2/a_z^2 = N^3 \lambda^2$ within LDA [17, 22, 23].

In the limiting case of impenetrable bosons, $\Lambda = 0$, the local chemical potential is equal to the Fermi energy, $\mu_{loc} = (\pi \hbar n)^2/(2m)$. This leads to the semicircular LDA density profile $n(z) = \sqrt{2N a_z^2 - z^2}(2N a_z^2 - z^2)/(\pi a_z^2)$, characteristic of the TG regime, see Fig. 1. Excitation spectrum of model (1) deep in the TG regime, $\Lambda \ll 1$, can be found perturbatively in $a_{1D}$. For that we use a mapping from the gas of strongly repulsive bosons to that of weakly attractive fermions [24]. A perturbative solution for the ground state energy is given in Ref. [25].

Analyzing the excited states results in the expansion [20]

$$\omega^2/\omega_z^2 \approx 4 \left(1 - C_N \sqrt{\Lambda}\right), \quad \Lambda \to 0,$$

(7)

where $C_N$ is calculated for all $N \geq 2$:

$$C_N = \frac{3\sqrt{2N} \Gamma(N - \frac{5}{2}) \Gamma(N + \frac{3}{2})}{\pi \sqrt{\pi} \Gamma(N) \Gamma(N + 2)} \times 3F_2 \left(\frac{3}{2}, -N, -N; \frac{7}{2} - N, \frac{1}{2} - N; 1\right).$$

(8)

The $\Lambda \to 0$ expansion of the LDA solution reproduces Eq. (7) and the coefficient $C_N$. Note that the coefficient $c$ entering Eq. (5) does not depend on $N$, while $C_N$ grows monotonously from $C_2 = 1/\sqrt{4\pi}$ to $C_\infty = 32\sqrt{2}/(15\pi^2) \approx 0.306$.

In the case $\Lambda \gg 1$, local chemical potential is of the Gross–Pitaevskii form, $\mu_{loc} = g_{1D} n$, and the shape of the density profile is given by Eq. (6), characteristic of the TF BEC regime. This implies $\omega/\omega_z = \sqrt{3}$.

In the case of arbitrary $\Lambda$ we solve the Lieb’s integral equations connecting $\mu_{loc}$ and $n$ numerically. We see from Fig. 3 that $\omega/\omega_z$ connects smoothly $\Lambda \ll 1$ (TG) and $\Lambda \gg 1$ (TF BEC) regimes [17]. We find that $\omega^2/\omega_z^2 \approx 3.3$ at $\Lambda = 1$, defined as a reference point separating these regimes (see Fig. 1).

**DMC simulations.** — How does $\omega/\omega_z$ depend on model parameters for small $N$, and how good are the Hartree approximation/LDA in that case? To answer these questions quantitatively we perform large-scale numerical simulations based on the diffusion Monte Carlo (DMC) algorithm [27]. This algorithm amounts to solving many-body Schrödinger equation in imaginary time and makes it possible to calculate ground-state energy to arbitrarily high precision. The convergence rate of the...
FIG. 3. (Color online) Ratio $\omega^2/\omega_z^2$, as a function of LDA parameter $\Lambda = N a_{1D}^2/a_z^2$. Dashed (black) line: the Hartree approximation for $N = 25$ in the equation $\Lambda = N^3 a_z^2$. Solid (black) line: LDA. DMC and experimental data points are the same as in Fig. 2. The TG regime corresponds to $\Lambda < 1$, as defined in Fig. 1.

Simulations can be enhanced greatly by doing an importance sampling with a guiding wave function $\psi_T$. We use $\psi_T(z_1, \ldots, z_N) = \prod_{j=1}^N \exp(-c_{\text{var}} z_j^2) \prod_{j<k} (|z_j - z_k| - a_{1D})$, with the parameter $c_{\text{var}}$ minimizing the variational energy. This function is known to work very well in a number of 1D systems [28–31].

We use the sum rule approximation (2), which only requires the knowledge of the ground state properties of the model. For the number of particles ranging from $N = 2$ to 25 we pushed DMC to its limits to perform high-accuracy simulations. Specifically, up to $10^4$ CPU hours were used to get each data point for $\omega/\omega_z$. The results obtained are shown as a function of $\Lambda$ in Fig. 2 and of $\Lambda$ in Fig. 3. Dashed lines interpolating the data points are obtained by using a Padé approximation and Eqs. (5) and (7) for the asymptotic values of $\omega/\omega_z$. We see in Fig. 2 that the Hartree and DMC curves are indistinguishable from each other for $\Lambda > 1$ at any $N$. The minimal value of $\Lambda$ at which these two curves are close to each other decreases with increasing $N$. It reaches the value $\approx 0.1$, and the minimal value of $\omega^2/\omega_z^2$ reaches $\approx 3.2$, at $N = 25$. We may thus locate the TF BEC regime of the model from Fig. 2 by setting where $\omega^2/\omega_z^2 \approx 3$. Figure 3 shows the same data points as in Fig. 2, as a function of the LDA parameter $\Lambda$. Evidently, LDA and DMC curves coincide for $\Lambda < 0.1$ at any $N$.

Comparison with experiments. — The Innsbruck group loaded three-dimensional (3D) BEC of $^{133}$Cs atoms into an array of 1D tubes formed by retro-reflected laser beams. The frequency of the external parabolic potential along the tube direction is $\omega_z = 2\pi \times 15.4$ Hz, and the maximal number of atoms per tube is about 25. The Innsbruck group data shown in Figs. 2 and 3 of the present Rapid Communication are taken from Ref. [16]. The ratio $\omega^2/\omega_z^2$ is taken from Fig. 3(a) of Ref. [16] and is shown as the large (blue) boxes in Figs. 2 and 3 of the present Rapid Communication. The temperature $T$ is obtained by requiring that the height of the thermal gas density profile at the trap center is equal to $n_0$. The parameter $T_{co}$ determines when the finite-temperature effects are important according to Ref. [33].

Rapid Communication are taken from Figs. 2 and 3(a) of Ref. [15] for $g_{1D} > 0$. We see that DMC simulations for $N = 17$ and 25 are compatible with the experimental data points. This match suggests that the temperature effects play little role in the experiment. The temperature $T$ of the 1D gas can be estimated by assuming that it is inherited from the 3D BEC, whose temperature is between 1 and 10 nK [32]. The degeneracy temperature of an ideal Bose gas, defined as $T_g = N\hbar \omega_z/k_B$ ($k_B$ is the Boltzmann constant) is about 18 nK. We see that $T$ is at least twice as low as $T_g$.

The ETH experiment examined what happens with the breathing oscillations if the temperature of the 3D BEC prepared to be loaded into an array of 1D tubes gets higher [14]. The parameters $a_{1D}$, $a_z$, and $N$ correspond to the TF BEC regime of the 1D gas. It was found that the breathing mode persists and $\omega^2/\omega_z^2$ grows from the value 3 to 4 (with the uncertainty about 0.1). These findings could be interpreted as the increase of $\omega$ due to the increase of the temperature of the 1D gas, assuming that it is in thermal equilibrium.

The Palaiseau group prepared a single tube with $^{87}$Rb atoms using atom-chip setup [16]. The number of atoms in the tube is given in Table I, and $\omega_z = 2\pi \times 9.0$ Hz. Data points from the Palaiseau group shown in Figs. 2 and 3 of the present Rapid Communication are taken from Fig. 3(a) of Ref. [16]. The parameters $a_{1D}$, $a_z$, and $N$ correspond to the TF BEC regime for all data points. We see that the frequencies for the first five of them match our theoretical predictions within the error bars. The frequencies for the last two of them are higher than the theory predicts. We get the gas temperature by comparing the height of the density profile in the tube center, $n_0$, calculated theoretically [34] with the one measured in experiment [16]. The values of $n_0$ and $T$ are given in Table I. According to Ref. [33], finite-temperature effects are relevant above $T_{co} = 3N\hbar \omega_z/[k_B \ln(\Lambda/4)]$ for

| Point | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
|-------|---|---|---|---|---|---|---|
| $N \times 10^{-3}$ | 7.8 | 6.8 | 5.8 | 3.2 | 2.3 | 1.9 | 1.4 |
| $n_0$ [μm$^{-1}$] | 66 | 58 | 52 | 33 | 23 | 18 | 13 |
| $\omega^2/\omega_z^2$ | 2.94 | 2.99 | 2.99 | 3.07 | 3.09 | 3.38 | 3.77 |
| $T$ [μK] | 0.40 | 0.40 | 0.34 | 0.23 | 0.21 | 0.21 | 0.19 |
| $T_{co}$ [μK] | 1.08 | 0.95 | 0.82 | 0.50 | 0.38 | 0.33 | 0.22 |
the range of parameters chosen in the experiment. We see from Table 1 that $T/T_{co}$ increases monotonously from the value $\approx 0.4$ for the first data point to $\approx 0.9$ for the last one. Note that $T_Q$ is nearly three times larger than $T_{co}$ (and, therefore, than $T$) for all data points. Thus, $T_Q$ may not define the crossover temperature in the experiment [16].

Summary. — We investigated the breathing mode frequency $\omega$ in model (1) at zero temperature by identifying the energy difference between a particular excited state and the ground state. This way we avoided dealing with the dynamical evolution of the initial state of the system. Our theory predicts the reentrant behavior of $\omega$ and fully explains the recent experiment [15] for the repulsive inter-particle interaction. The extension of the present theory to the finite-temperature case requires a separate study. The existing phenomenological approaches [16, 35] are yet to be tested against the predictions from the exact dynamical evolution of the system.

We thank the Palaiseau group [16] for providing access to their experimental data and the Innsbruck group [15] for numerous enlightening discussions. The Barcelona Supercomputing Center (The Spanish National Supercomputing Center – Centro Nacional de Supercomputación) is acknowledged for the provided computational facilities. The work of A.Iu.G. was supported by grant from Region Ile-de-France DIM NANO-K. G.E.A. acknowledges partial financial support from the DGI (Spain) Grant No. FIS2011-25275 and Generalitat de Catalunya Grant No. 2009SGR-1003.
