Assessing Population Trend and Risk of Extinction for Cetaceans Lacking Long-Term Census Baselines

Shiang-Lin Huang*
Department of Environmental Biology and Fishery Science, National Taiwan Ocean University, Keelung, Taiwan

Abstract
Assessment of population trend and risk of extinction, essential for informed conservation, needs baselines including percentage of population decline, extent of occurrence, population size, population structure and probabilities of extinction. Construction of these baselines usually claims long-term census efforts that are often insufficient or even lacking for many cetaceans, especially for those nearby rapidly developing countries. Restricted to variation from current census techniques, however, the approach based on long-term census database is unlikely to detect early or recent sign of population decline. Here, I propose an integrative perspective, the systematic demographic analysis, to solve life history and demographic parameters essential for status and risk assessment for the cetacean populations. Transect technique with the aid of GPS records and environmental characteristics can be used to estimate population abundance and figure the extent of occurrence and critical habitat, information essential for sound habitat protection. Capture-mark-recapture technique based on the database from individual photo-ID histories can be used to estimate population size, apparent survival rate and life history parameters. Collections of stranded and by caught carcasses can be used to solve life history parameters, age-specific survivorships or mortality rates and population genetic diversity indirectly relating to population size. Applications of population viability analysis to above parameters such as VORTEX model or other individual-based stage/age matrix model that factors the stochasticity and uncertainty can be used to solve the likely range of rate of decline and extinction risk of threatened population. Finally, I emphasize the need to integrate the histories of long-term land use and landscape change when formulating habitat management programme for the rare and/or endangered populations to avoid skipping the low-sighting habitat from intense anthropogenic impacts.

Keywords: Trend Analysis; Demography; Census; Capture-Mark-Recapture Modeling; Environment Change

Introduction
Ideally, the precautionary principle of conservation calls necessary actions to prevent or mitigate any threat that is possible to endanger the long-term survival of a population, even if the interaction between threats and population survival has not yet been clearly elucidated. In actual, however, conservation awareness and practice still awaits the clear signs of endangerment of population survival. In many developing countries, the awareness that the population survival is end angered often arises from evidences like once frequently sighted animals become rare [1] or the implementation of immense environment-developing project will change/is changing natural habitat. In this scenario, the conservation measures often fall behind the pace of population decline and often passively mitigate the obvious threats, the ‘crisis management’ perspective, rather than actively minimize and ameliorate the endangerness of survival, the ‘crisis prevention’ perspective. When dealing with conservation of rare or threatened species/populations, policy makers, stakeholders and scientists frequently ask: What is current status of the species/population concerned? How fast is the current population decline? What is the chance the endangered species or population becomes extinct in future? How many years do we still have to reverse population decline? Answers to these questions lead to the assessment of population status and extinction risk. In the IUCN Red List Categories and Criteria Version 3.1 [2], the risk of extinction and hence population status, either NT (Near Threatened), VU (Vulnerable), EN (Endangered) or CR (Critically Endangered), is classified by a set of quantitative baselines, including percentage of population decline, extent of occurrence or occupancy, population size, population (age) structure and probabilities of extinction within a given time (Table 1).

To construct these baselines usually claims long-term census efforts [3-6] that are often insufficient or even lacking for many cetaceans, especially for those in rapidly developing countries. The baselines for status and risk assessment of the threatened populations/species can be approached by several techniques in cetaceans, from long-term and periodical census monitoring [7] to meta-analysis of stranded and/or by caught carcass collections [8,9]. Careful use of these techniques with sufficient attention on their theoretical assumptions and limitations can facilitate stepping up conservation efforts and moving on from precautionary management to informed conservation strategies. It is my goal to summarize the techniques frequently used to solve the population trend and status/risk assessment in many cetaceans. This summarization could be helpful for the conservation of cetaceans for forming sound conservation actions, especial for the species inhabiting freshwater habitats and coastal waters under intensive anthropogenic threats [10-17] in developing countries.

Long-term census: How long is enough?
Theoretically, the population trend can be solved by applying regression modeling to long-term census records [4-6,18,19]. In practice, however, the variation from field techniques restricts the resolution of census records to estimate the population trend. There are some studies report population trends by a simple application of statistical methods to historic abundance estimates [4-6,18,19]. However, this...
goals and classify population status under Criterion A2 of the IUCN Red List Categories and Criteria Version 3.1 [2].

The PE estimate itself becomes another alternative to census technique is needed to approximate population trend and status. Cut-off lines represent the boundary conditions meeting the classifications of CR (Endangered) or EN (Vulnerable) and CR (Critically Endangered) under Criteria A - E of the IUCN Red List Categories and Criteria version 3.1 [2].

91 Exercise should be viewed very cautiously as they may yield statistically "significant" yet actually biased and potentially misguided results [18-22]. Such arbitrary conclusions should be of particular concern when the abundance estimates have high variation. [20] Described a power analysis to test if a long-term census database has sufficient "power" to describe a trend. [21] Based on the power analysis indicates that the time needed to detect population change in field (either increase or decrease), $T_d$, via annual census frequency is determined by the CV of census records and average rate of population change ($r$): 

$$T_d = 5.38 \times CV^{2/3} \times r^{-2/3}$$

(1)

[17] Further calculated the $T_d$s needed to detect population decline and classify population status under Criterion A2 of the IUCN Red List Categories and Criteria Version 3.1 [2]. A minimum of a decade of census effort is needed to detect a trend meeting the standard to classify CR (Figure 1) while a slower rate of decline and hence a classification at EN (Endangered) or CR (Critically Endangered) status under $IUCN$ Criterion A2, where population decline is higher than 30% (VU), 50% (EN) or 80% (CR) of initial abundance within three generations for cetaceans [2].

Thus, even though long-term census history theoretically can be used to reflect population trend, this technique is unlikely to disclose early and/or recent population decline in practice even the census works have been well designed and implemented. Worse, systematic census surveys are seldom implemented across the entire geographic range of a population until the population decline, or anthropogenic impacts, become explicitly apparent, as tragically exemplified by the recent history of the decline and extinction of baiji ($Lipotes vexillifer$) and Yangtze finless porpoise $Nosehoca asiatica$) associated research efforts [23-25]. In case the population decline associates with the increasing anthropogenic impacts, the delayed response of population decline due to the restriction from variation from census techniques may result in difficulties to restore habitat quality and reverse a decline [17]. For the cetacean populations lacking periodical census baselines, method alternative to census technique is needed to approximate population trend and status.

Demography approach of trend and status assessment

Based on survival-reproduction modeling demographic approach provides an indirect way to estimate population trend and, particularly, forecast the risk of extinction, including the probabilities (PE) and date (TE) of extinction, under assumed scenarios for threatened species/populations [7-9,26]. The PE estimate itself becomes another
quantitative assessment of population status under Criterion E of the IUCN Red List Categories and Criteria Version 3.1 [2].

Recent studies of trend projections show the usefulness of demographic approach in quantifying the survival risk of an endangered population. Mei et al., [9] reports that the Yangtze finless porpoise has been declining since the late 1970s but the rate of population decline has been accelerating since the early 1990s, from lower than 2% abundance per annum before 1993 to faster than 6% abundance per annum after 1993. Meta-analyses of data collected by systematic boat surveys in the mainstream of the Yangtze River between 1990 and 2007 [24, 27] estimate an average of 6.4% decline of abundance per annum [9]. The consistency of results from two independent studies applying different methodological approaches, demographic approach and traditional census technique, demonstrates the power of demographic analyses.

The interpretation of demographic analysis, however, should be cautious especially when applied to threatened populations that are endangered by escalating anthropogenic impacts. Most demographic models assume that current environmental conditions do not change much over time [28-30]. In reality, environmental conditions may and often do change with time, thus altering the risk of local extinction in future. Species or populations usually begin attracting conservation attention only after they are exposed to severe environmental degradation or habitat loss, or when once common animals are not seen frequently anymore. In such instances, the animals may indeed have been struggling for their long-term biological survival in the face of environmental uncertainty of exponentially deteriorating habitats [17] that are closely related to exponentially increasing economic and human population growth [31-34]. The survivorship of threatened species or populations predicted by demographic analyses should be viewed as optimistic compared to the true survivorship. This risk can be particularly critical in rapid developing countries where cetaceans inhabit waters nearby intense human activities including urbanization, industrialization and long-term coastal change (Figure 3).

To run demographic analysis two sets of quantitative baselines are needed before applying the survival-reproduction modeling: the age-specific reproductive rates, \( m(x) \), and age-specific survivorship, \( l(x) \). The \( m(x) \) can be approximately defined as follows: [35]

\[
m(x) = 0, \ 0 \leq x < Am (2)
\]

\[
m(x) = \frac{\varphi}{R1}, \ Am \leq x < Ax
\]

Calving interval, and represents expected proportion of female calves (often assumed to be 0.50) [8,9,17]. Values or ranges of \( Am, CI \) and \( Ax \) need direct feedback from life history studies through the analysis of reproductive status at various ages [8,36-38] or the long-term capture-mark-recapture (CMR) exercise by individual photo-ID histories [39-41].

The \( l(x) \) can be constructed by life-table analysis or CMR exercise. In the life-table approach, life table parameters including the number of alive at age \( x (n_x) \), proportion surviving to age \( x (l_x) \) and mortality rate at age \( x (q_x) \), can be calculated using a standard method based on the age-at-death database (Table 2) [8,9,42-44]. For cetaceans I recommend the application of Siler’s model [45] to calculated \( l(x) \) to

\[
\text{Figure 2: } \% \text{ of abundance loss when abundance declines become detectable at different levels of abundance estimate CV.}
\]

\[
\text{Figure 3: Long-term landscape change along Shenzhen coast, Guangdong Province, China, from 1973 to 2013, indicating significant coastal habitat loss due to land reclamation and substantial landscape change to urbanization. Band composition: RGB231 for Landsat 1 MSS (1973) and RGB753 for Landsat 8 OLI (2013).}
\]
build a age-specific survivorship model, \( l(x) \), with quantifiable range of uncertainties [8,9,43]. In the Siler’s model, age-specific survivorship, \( l(x) \), is determined by three components:

\[
l(x) = l_1(x) \times l_2(x) \times l_3(x) (3),
\]

including an exponentially decreasing risk due to juvenile risk factors

\[
l_1(x) = \exp(-a_1/b_1(1-\exp(-b_1\times x))) (3.1),
\]

a constant risk experienced by all age classes

\[
l_2(x) = \exp(a_2\times x) (3.2),
\]

and an exponentially increasing risk due to senescent risk factors,

\[
l_3(x) = \exp(r/b_3(1-\exp(b_3\times x))) (3.3),
\]

Where \( x \) is the age and \( a_1, b_1, a_2, a_3, \) and \( b_3 \) are the Siler’s parameters that can be estimated through statistical process such as non-linear regression modeling.

The life-table approach to estimate population trend usually needs massive collection of age-at-death data while the construction of \( l(x) \) and following \( l(x) \) is highly sensitive to the evenness of data collection. A data-collection network run by research institutes, local governments and conservation groups is needed to facilitate the collection of stranded or by caught carcasses in a systematic way.

In the CMR exercise, \( l(x) \) can be constructed by

\[
l(x) = Sc \times Sa^{-1} (4),
\]

where \( Sc \) and \( Sa \) are the survival rates of calf (\( x \leq 1 \)) and non-calf animals [17]. Both \( Sc \) and \( Sa \) can be solved by photo-ID histories [14,29,46-49]. An iterated simulation run by re-sampling survival rates (\( Sc \) and \( Sa \) both and independently) within their lower-upper limits may be introduced to factor in the uncertainties with quantifiable ranges.

**Systematic demographic analysis: an integrative perspective**

One of the difficulties in constructing population baselines for status and risk assessment for the threatened species or populations comes from the lack of representative database with sufficient resolution to estimate demographic parameters. As previously described traditional census techniques requires decade of survey efforts to construct a database to estimate population trend. The life history study and demographic analysis, on the other hand, need extensive and often long-term data accumulation from either carcass collection or photo-ID histories. In general case these studies may be implemented by different research teams that use different sampling and analyzing processes, which brings another difficulty in constructing quantitative baselines: insufficient connection of demographic parameters among different researches.

Here, I propose an integrative perspective, the systematic demographic analysis (SDA), for the cetacean populations lacking quantitative baselines essential for status and risk assessment (Figure 4). Implementation of systematically-designed census exercise can provide quantitative baselines in an integrative way. The implementation of transect survey, with the information of GPS and animal-sighting records at each sampling sites, does not only estimate the population abundance inside the survey area but also figures the extent of occurrence by minimum convex polygon (MCP) and core/critical distribution site (such as 50% kernel density estimate), information essential for sound protected area design [13,16,50-54]. Database from individual photo-ID histories can be used to estimate population size, apparent survival rate and, dependent on the temporal scale of database, life history parameters including \( Am, Rl \) and \( Ax \). Database of age-reproductive status records collected from stranded and by caught carcasses can be used to solve both life history parameters and age-specific survivorships or mortality rates. With the help from genetic diversity analysis the collection of carcasses can further provide information of population genetic diversity [55-58], which is an indirect measurement of extinction risk of a threatened population [59-61].

The rate of decline can be solved by calculating the finite rate of increase (\( \lambda \)) in deterministic perspective:

\[
\lambda = \exp(r) (5)
\]
Caution when basing conservation actions on census data

In many developing countries the awareness and implementation of cetacean conservation often lags behind the actual degree of population decline and the extent of increasing anthropogenic impacts [17]. Thus, the ‘baselines’ received from field census survey may actually have been affected by anthropogenic impacts rather than the initial and unaffected status of a population. The Yangtze River dolphin, or baiji (Lipotes vexillifer), has been known continuously decline since the 1970s [24]; however, answer to the question: if baiji is still survival cannot be assured until the full-scaled census in 2006 [23,24]. The actual date when baiji became extinct definitely happened prior to 2006 but is unlikely to approach.

Pattern of spatial distribution (MCP, 50% kernel density, the association with environmental characteristics) can be used to identify key habitat for protection. In the rapid developing countries, however, the animal distribution, especially the cetaceans inhabiting coastal or freshwater habitat, may have been affected by long-term environmental change when the census was implemented. For example, Zhao et al., [62] considers a priority area for Yangtze finless porpoise conservation at a section where porpoise sightings are high but no in situ reserve has been enacted [9,63]. On the basis of remotely-sensed satellite imagery, however, the spatial-demography analysis between spatio-temporal water quality change and Yangtze finless porpoise distribution indicates that it may be the extent of habitat deterioration relating to extent of eutrophication rather than different habitat preference (or quality) forming current distribution gradient of Yangtze finless porpoise in the Yangtze River (Huang SL, unpublished materials).

Direct use of animal distribution pattern from census in areas with intense human activities may mislead the strategy of habitat protection policy in cetacean conservation. The conservation of humpback dolphins off western Taiwan coast (WTC) has received high local awareness [13,63-64]. Baselines from series census indicate a very small number of population size [66] and discontinuous distribution pattern (Figure 5) [63-64]. The distribution pattern of WTC humpback dolphins, two regions of a relatively high sighting frequency separated by a stretch of coast where the animals are seen sporadically, is translated into two “hot-zones” connected by a "migratory corridor" [63-64], which guides the formulation of habitat management strategy for the humpback dolphin conservation [66]. Analysis of Landsat imagery since the 1970s, however, reveals significant coastal change, especially large-scaled land reclamation in central WTC (Figure 6). Calculations on the area of land reclamation since the 1970s through Landsat imagery indicate rapid loss of coastal habitat due to land reclamation between 1980 and 2000, mostly in the central WTC, while the land reclamation reach ‘ceiling’ stage after 2000. The systematic survey of distribution and census of WTC humpback dolphins, on the other hand, was not implemented until 2006. The ‘baselines’ currently used for habitat and population management indeed came from the impacted population.
Conclusions

Population trend is the baseline essential for status and risk assessment in conservation of rare and/or endangered animals. Theoretically the population trend can be estimated by the long-term census database; however, the applicability of census approach in estimating population trend is restricted by the variation (CV) from currently-used census techniques. Power analysis indicates that it will need decades of census effort to detect the change of population size in field, which is unlikely a practical way for the cetacean populations lacking census baselines. Demographical approach, on the other hand, provides an alternative way to estimate population trend and, particularly, forecast the rate of decline and risk of extinction (PE and TE) under assumed scenarios. To apply demographic method two sets of population baselines are needed: the age-specific reproductive rates, \( m(x) \), and age-specific survivorships, \( l(x) \) that can be solved by analyzing database from individual photo-ID histories or age-at-death records from collected carcasses. A systematic design and application of above methods, the systematic demographic analysis, can provide quantitative baselines, including life history parameters \((Am, RI, A_x)\), \( m(x) \) and \( l(x) \), in an integrative way for the cetacean populations lacking population baselines. Then, modeling exercise of population viability analysis factoring in parameter uncertainty and demographic stochasticity can be applied to solve the rate of decline and risk of extinction. Finally, I emphasize the need to integrate the histories of long-term land use and landscape change relating to land reclamation, urbanization and industrialization to avoid the skip of low-sighting habitat from intense anthropogenic impacts when formulating habitat management programme based on the feedbacks from census.
