\textbf{Abstract}

\textbf{Aim:} To compare ab interno trabeculectomy by trabecular meshwork (TM) excision to plasma-mediated ablation in primary open-angle glaucoma (POAG) patients.

\textbf{Methods:} Retrospectively collected data of TrabEx+ (TEx) \((n = 56)\) and Trabectome (T) \((n = 99)\) patients were compared by coarsened exact matching to reduce confounding and matched based on baseline intraocular pressure (IOP) and age. The primary outcomes were IOP and the number of glaucoma medications. Complications and the need for additional glaucoma surgery were assessed. Patients were followed for up to 1 year.

\textbf{Results:} A total of 53 TEx could be matched to T. Baseline IOP was 16.5 ± 4.6 mm Hg in both; age was 73.7 ± 8.8 and 71.5 ± 9.9 years in TEx and T, respectively. TEx was taking more medications than T \((p < 0.001)\). IOP was reduced to 14.8 ± 4.3 in TEx and to 13.4 ± 3.4 in T at 6 months, and to 14.9 ± 6.0 \((p = 0.13)\) in TEx and to 14.1 ± 3.8 mm Hg \((all\ p < 0.05)\) in T at 12 months. Medications were reduced at both 6 and 12 months \((p < 0.05)\). No differences were seen between TEx and T at 6 and 12 months. In TEx, only one serious complication occurred, and two patients required further glaucoma surgery.

\textbf{Conclusion:} Although both groups had a baseline IOP considered low for ab interno trabeculectomy, IOP and medications were reduced further at 6 and 12 months. IOP reduction did not reach significance in TEx at 12 months. The intergroup comparison did not reveal any significant differences. Both had a low complication rate.

\textbf{Clinical significance:} This study investigated subtle differences between a plasma-ablative device, the T, and an excisional device, the TEx, by applying coarsened exact matching. IOP and medications were reduced in both groups at 6 and 12 months, although IOP reduction did not reach significance in TEx at 12 months. The intergroup comparison did not reveal any significant differences, with both devices having a low complication rate.

\textbf{Introduction}

Ab interno ablation, excision, and disruption of the trabecular meshwork (TM) can lower IOP effectively in primary open-angle glaucoma (POAG) when the outflow resistance is at the most proximal part of the conventional outflow tract.\textsuperscript{1} Secondary open angle glaucomas (OAGs) with a pathomechanism that principally affects the TM respond to these procedures equally well (pigmentary,\textsuperscript{2,3} and anti-VEGF agent-induced\textsuperscript{4} glaucoma) or better than POAG (pseudoxfolliation,\textsuperscript{5} steroid-induced glaucomas).\textsuperscript{6}

Plasma-mediated ablation of the TM with the T (MicroSurgical Technology, Redmond, Washington, United States of America) has been available to surgeons since 2004,\textsuperscript{7} while excisional removal was first introduced in 2014.\textsuperscript{8,9} Interestingly, dual blade excision of tissue in the angle was invented earlier (1989), but was only used to obtain biopsies.\textsuperscript{10} Current leading modalities of excisional TM removal are the TEx (MicroSurgical Technology, Redmond, Washington, United States of America) and the Kahook Dual Blade (KDB) (KDB, New Word Medical, Rancho Cucamonga, California, United States of America). The absence of a bleb and the theoretical limit of maximal IOP reduction to the level of episcleral venous pressure constitute important safety features of T, TEx, and KDB because they avoid hypotony or bleb-related complications so common to filtering surgeries.\textsuperscript{11}

There are advantages to both plasma-mediated ablation (T) and dual blade excision (TEx and KDB). T enables the atraumatic molecularization and aspiration of the TM.\textsuperscript{11} In contrast, TEx and KDB can be used to obtain TM samples\textsuperscript{2} and excise the TM without the need to purchase a high-frequency alternating current generator as an additional external device. An advantage of TEx over the KDB is the active irrigation and aspiration that improve visibility and anterior chamber stability.\textsuperscript{2} A downside of both the TEx and KDB is that a dual cut of the TM cannot always reliably be initiated, potentially allowing remaining TM lips to reapproximate, as can happen in trabecular disruption by trabeculotomy.\textsuperscript{13} Literature regarding TEx is limited to studies of its efficiency in obtaining TM biopsies in vivo\textsuperscript{9} and ex vivo porcine anterior segments.\textsuperscript{12,14}
Given the effectiveness of excisional ab interno trabeculectomy in clinical studies, we hypothesized that subtle differences between T and TEx could be discovered by applying a modern statistical method to existing data in the form of matching. Matching reduces confounding factors by enabling a highly balanced comparison. In two studies where matching was used, we found that T performed significantly better than trabecular micro-bypass implants. This is something that can be obscured when unmatched averages are compared and are not eliminated by, for example, comparing two procedures in the fellow eyes of the same individual.

**Methods**

This study was approved by the institutional review board (IRB) of the University of Würzburg (protocol ID: 21122020 1920). Due to its retrospective nature, informed consent was waived. The study abided by the principles stated in the declaration of Helsinki and its subsequent amendments. We performed a chart review of all patients with OAG who had undergone surgery in our center from February 2020 to 2021. The surgical indication for T and TEx was an IOP value above the target level on maximally tolerated topical treatment or a desire to reduce the number of glaucoma medications. Those with a follow-up of 6 months or longer were matched using coarsened exact matching (CEM). We excluded patients with secondary glaucoma and those with a follow-up of fewer than 6 months. Patients younger than 20 years of age or who underwent prior glaucoma surgery on the same eye were also excluded.

Baseline parameters recorded included age, gender, type of glaucoma, date of surgery, visual acuity, IOP, and the number of IOP-reducing medications. Data on postoperative complications and subsequent ocular surgeries were also gathered. Visual acuity, IOP, and the number of medications were obtained one day before surgery, as well as at each follow-up visit. All IOP measurements were carried out using Goldmann applanation tonometry (Haag-Streit, Koniz, Switzerland). Surgical success was defined as a total IOP decrease of ≥20% with a final IOP of ≤21 mm Hg. In addition, patients who had a medication reduction of one or more were also considered to have undergone a successful intervention.

The patient’s head was tilted 45° away from the surgeon. After a temporal clear-corneal incision, light pressure was applied to the posterior lip of the incision to release a small amount of aqueous humor. The resulting hypotension caused venous blood to reflux into Schlemm’s canal (SC) and helped identify the proper target. The tip of the instrument was inserted. The TM was visualized with a goniolens and then ablated (T) or excised (TEx) along approximately 120° of the nasal circumference. Subsequent blood reflux indicated a successful removal of the TM and the inner wall of SC. After retraction of the instrument, the anterior chamber was reformed by injecting a balanced salt solution, and the corneal incision was sealed by hydration. The postoperative treatment was similar for both procedures and consisted of dexamethasone eye drops tapered by one drop per week and antibiotic eye drops for 1 week; glaucoma drops were continued as deemed necessary.

**Statistical Analysis**

Our power calculation indicated that 48 patients would be needed in the TEx group to compare them to T patients and achieve a statistical power of 80%. Data were analyzed using Statistical Package for the Social Sciences statistics (version 26, IBM, New York, United States of America). Means and standard deviations were calculated for continuous variables, while frequencies and percentages were used for categorical variables. The Kolmogorov-Smirnov test was run to test for the normal distribution of data. Patients were matched by IOPBL and age, the two most important determinants of postoperative IOP. To compare the means of the primary outcome parameters, a t-test or a Mann–Whitney U test was used. Surgical success was reported as a dichotomous variable and compared using a Chi-squared test. A p-value of 0.05 or less was considered statistically significant.

**Results**

Of 75 TEx patients, 53 could be matched to T by age and IOP using CEM. Table 1 shows the baseline characteristics of the matched groups. There were no differences in age, gender, glaucoma type, baseline IOP, and visual acuity between both groups (all p-values >0.05). Matched baseline IOP was at 16.6 ± 4.6 mm Hg (p = 0.97). Age was 73.7 ± 8.8 years in TEx and 71.9 ± 9.9 years in T (p = 0.24). TEx was taking more medications, 2.1 ± 1.4, than T with 1.4 ± 1.1 (p < 0.001). Most patients (>80% in both groups) had a simultaneous phacoemulsification/intraocular lens insertion (phaco/IOL) with their TEx or T procedure. POAG patients represented the majority, 73.6%, in both groups; LTG comprised the remaining 26.4%.

From a baseline IOP of 16.6 ± 4.6 mm Hg, our 6 months postoperative mean IOP has reduced to 14.8 ± 4.3 mm Hg in TEx, and 13.4 ± 3.4 mm Hg in T. Both values were significantly lower than baseline (p < 0.01 for both). At 12 months, IOP levels in TEx were similar to baseline (14.9 ± 6.0, p = 0.135). T was significantly lower than baseline (14.1 ± 3.8, p < 0.001). Both groups took significantly fewer medications; the number of medications at baseline increased to 2.1 ± 1.4 in TEx compared to 1.4 ± 1.1 in T (p < 0.001). The difference in visual acuity was not statistically significant.

**Table 1:** Matched baseline characteristics of TEx and T

| Variable     | TEx+ (n = 53) | T (n = 53) | p-value TEx vs T |
|--------------|--------------|------------|------------------|
| Age (years)  | 73.7 ± 8.8   | 71.5 ± 9.9 | 0.24             |
| Female (n, %)| 31 (58.5%)   | 29 (54.7%) | 0.7              |
| Male (n, %)  | 22 (41.5%)   | 24 (45.3%) |                 |

Comparing Excisional to Plasma-ablative Ab Interno Trabeculectomy

Both TEx and T showed a significant postoperative IOP decrease at 6 and 12 months (Table 2, both p < 0.005). In the inter-group comparison, IOP levels at the 6 and 12-month follow-ups were similar (p = 0.12 and p = 0.99, respectively; Table 2). TEx used more glaucoma medications compared to T (p < 0.001 for both 6 and 12 months). IOP reduction at 6 months was 2.0 ± 5.0 mm Hg in TEx and 3.2 ± 4.8 mm Hg in T. These values at 12 months were 0.6 ± 5.9 mm Hg in TEx and 2.4 ± 4.8 mm Hg in T. There was no significant difference in IOP reduction between both groups at 6 or 12 months (p = 0.41 and 0.2, respectively). Medication reduction in TEx and T was 0.43 ± 1.3 and 0.88 ± 1.4 at 6 months and 0.63 ± 1.29 and 0.75 ± 1.25 at 12 months, respectively. These values did not differ significantly between both groups (p > 0.05).

Table 3 depicts the unmatched data for each group. There was a significant difference in age between TEx and T patients (p < 0.005). Similarly, to our matched data, compared to their baselines, TEx and T used fewer medications 6 and 12 months postoperatively (all p-values <0.05), and T needed fewer medications than TEx at both follow-ups (both p < 0.001*).

Applying success criteria common to minimally invasive surgeries, an IOP decrease of ≥20% or final IOP < 21 mm Hg, TEx, and T were at or exceeded 93% at 6 months and 95% at 1 year (Table 4; p > 0.05 for TEx vs T). Using the more stringent criteria of IOP decrease of ≥20% and final IOP ≤ 21 mm Hg, success was achieved in more than 40% at 6 months and in more than 32% at 1 year. Success in both IOP reduction and at least one medication reduction was achieved in 15.2% in TEx and 13.5% in T at 6 months. These values were 10.0% (TEx) and 7.7% (T) at 1 year, respectively.

Four (7.5%) TEx patients experienced postoperative complications that included toxic anterior segment syndrome.

### Table 2: Follow-up parameters compared between TEx and T

| Variable/group | TEx (n = 53) | T (n = 53) | p-value TEx vs T | p-value baseline vs follow-up (TEx/T) |
|----------------|-------------|-------------|------------------|-------------------------------------|

Comparing Excisional to Plasma-ablative Ab Interno Trabeculectomy

Comparing Excisional to Plasma-ablative Ab Interno Trabeculectomy

In this study, we applied CEM to compare the 1-year outcomes of excisional ab interno trabeculectomy between a newer dual-blade device (TEx) and established plasma-mediated ablation (T) (Fig. 1). The advantage of matching is that small IOP differences caused, for instance, by wound healing can be detected. Using matching, we previously found that an IOP increase seen in trabecular bypass stents is absent in ab interno trabeculectomy.\(^\text{18,19}\) We had observed the difference in IOP reduction around the time a foreign body reaction and fibrosis were observed in other trabecular bypass studies, suggesting this may be the underlying cause.\(^\text{22,23}\)

For the present study, we had chosen IOP\(_{\text{BL}}\) and age as the matching criteria because they are the two most important determinants of postoperative IOP, which can diminish the IOP reduction according to the formula 0.73 mm Hg × baseline IOP plus 0.03 mm Hg × age.\(^\text{21}\) In contrast, the preoperative number of medications affects the postoperative IOP result only in a minor way, by lessening the response by 0.09 mm Hg × number of medications.\(^\text{21}\) Because the difference in the average medication intake was only 0.7 drops, we would expect the IOP reduction difference to be negligible (0.063 mm Hg). The match caused our patient baseline demographics to have the same baseline IOP and sufficient similarities in the other variables not to be significantly different, except for the medication intake. Patients who underwent TEx were taking more medications than T. This could imply that the pressure in these patients was more refractory to medical treatment than in T. It is important to point out that this would not have disadvantaged TEx. On the contrary, it is often eyes with more advanced glaucoma, not milder glaucoma, that have a larger response to AIT, possibly because their TM is more diseased and less permeable.\(^\text{5,24}\) When this larger resistance is removed, a greater total IOP decrease can ensue.

\(n = 1\) and cystoid macular edema (CME) \(n = 3\). Two patients (3.8%) required further glaucoma surgeries and received a micro shunt (Preserflo, Santen, Osaka, Japan, \(n = 2\)). One T patient experienced postoperative CME (1.9%).

**Discussion**

Figs 1A and B: Mean intraocular pressure (IOP) and number of medications for TEx (blue) and T (red). (A) T and TEx had a low baseline IOP. An IOP reduction occurred in both, but was more pronounced in T. (B) TEx took more medications than T at baseline. A reduction in medications was achieved in both T and TEx, and to a similar extent. IOP\(_{\text{BL}}\), IOP at baseline; IOP\(_{\text{p6}}\), IOP at 6 months; IOP\(_{\text{p12}}\), IOP at 12 months; Med\(_{\text{BL}}\), number of medications at baseline; Med\(_{\text{p6}}\), number of medications 6 months after surgery; Med\(_{\text{p12}}\), number of medications 1 year after surgery; SE, standard error

Comparing Excisional to Plasma-ablative Ab Interno Trabeculectomy

postoperative IOP. Using a hypothetical patient, a 75-year-old pseudophakic patient with POAG and a baseline IOP of 21 mm Hg on two medications, 16.8 mm Hg would be expected. TEx and T appear to be most appropriate for patients who already have a low preoperative IOP if they want to avoid the complications of filtering surgery. It is also appropriate for those who primarily need cataract surgery but also want to give IOP and medication reduction a chance at the same time. As the low rate of patients who fulfilled both the IOP and the medication success criteria (8–15%) highlights, the riskier trabeculectomy may be better able to achieve freedom from drops and reduce the IOP by a large amount. The reduced success rate of T in the setting of a low preoperative IOP has already been established before in other studies.

Despite similar baselines and TEx patients taking more medications to achieve this IOP, there was no statistically significant difference between the postoperative IOP of TEx and T when compared directly. The IOP reduction in TEx was significant at 12 months in the unmatched data, but the focus of our study was to detect differences in outcomes of two already quite similar surgical modalities. The IOP reduction in TEx appeared not to be statistically significant at 12 months in the matched comparison because the match eliminated unmatched data and also because of the low baseline IOP. A low baseline IOP increases the number of subjects required to detect a before-after difference while maintaining sufficient statistical testing power. A medication washout is often performed in clinical trials with a prospective design for this reason. At first glance, the IOP reduction seemed larger at 12 months in T than in TEx, but this has to be interpreted with caution since the comparison of both groups did not show a difference. It is possible that these differences exist but remain undiscoverable with the numbers used here and are, therefore, not clinically relevant. A truly larger IOP reduction in T could have pointed towards a less traumatic TM ablation with this technique. Plasma-mediated ablation is drag free, while dual blade ablation requires that the TM be put under stretch before the cut can be initiated. It is a common occurrence during surgery with the TEx and KDB that drag transmits to the ciliary body band via processes that insert into the TM. Occasionally, this can cause a shallow and inconsequential cyclodialysis to form. It is also not unusual for excisional devices to catch the scleral spur, the outer wall of SC, or the innermost part of the roof of SC, potentially causing trauma. A full TM strip can also not always be excised, which causes the procedure in such patients to be more akin to a traditional goniotomy, including a chance that TM lips might reapproximate as is known to occur in trabeculotomy. These concerns do not exist with T.

As is common to minimally invasive glaucoma surgeries in general, only a handful of complications occurred, too few for a meaningful statistical comparison. Both TEx and T can be considered very safe as only one serious and temporary complication occurred, toxic anterior chamber syndrome, that resolved with medical treatment. In comparison to our complications of 7% in TEx and 2% in T, previous KDB studies reported complication rates ranging from 7 to 14%.

Our study had several limitations. The design was chosen in order to display small, device-specific differences between T and TEx, a plasma-mediated and excisional removal technique of TM, respectively. A small IOP and medication reduction occurred in both, despite a relatively low baseline IOP. There were no major device-specific differences.

**Conclusion**

In conclusion, this study applied coarsened exact matching to display small, device-specific differences between T and TEx, as seen in prior studies. Same-session cataract surgery does not have a clinically significant impact on T. While it is reasonable to assume that the same applies to TEx, this has not been established yet.

**Clinical Significance**

This study investigated subtle differences between a plasma-ablative device, the T, and an excisional device, the TEx, by applying coarsened exact matching. IOP and medications were reduced in both groups at 6 and 12 months, although IOP reduction did not reach significance in TEx at 12 months. The intergroup comparison did not reveal any significant differences, with both devices having a low complication rate.
