Two High Throughput Screen Assays for Measurement of TNF-α in THP-1 Cells

Kristin P. Leister, Ruili Huang, Bonnie L. Goodwin, Andrew Chen, Christopher P. Austin and Menghang Xia*

NIH Chemical Genomics Center, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD 20892, USA

Abstract: Tumor Necrosis Factor-α (TNF-α), a secreted cytokine, plays an important role in inflammatory diseases and immune disorders, and is a potential target for drug development. The traditional assays for detecting TNF-α, enzyme linked immunosorbent assay (ELISA) and radioimmunoassay, are not suitable for the large size compound screens. Both assays suffer from a complicated protocol, multiple plate wash steps and/or excessive radioactive waste. A simple and quick measurement of TNF-α production in a cell-based assay is needed for high throughput screening to identify the lead compounds from the compound library. We have developed and optimized two homogeneous TNF-α assays using the HTRF (homogeneous time resolved fluorescence) and AlphaLISA assay formats. We have validated the HTRF based TNF-α assay in a 1536-well plate format by screening a library of 1280 pharmacologically active compounds. The active compounds identified from the screen were confirmed in the AlphaLISA TNF-α assay using a bead-based technology. These compounds were also confirmed in a traditional ELISA assay. From this study, several beta adrenergic agonists have been identified as TNF-α inhibitors. We also identified several novel inhibitors of TNF-α, such as BTO-1, CCG-2046, ellipticine, and PD 169316. The results demonstrated that both homogeneous TNF-α assays are robust and suitable for high throughput screening.

Keywords: AlphaLISA technology, HTRF technology, inhibition of TNF-α production, qHTS, TNF-α, 1536-well plate.

INTRODUCTION

There are three members in the family of tumor necrosis factors (TNF): TNF-α, TNF-β (also called lymphotixin α, LT-α) and LT-β [1]. TNF-α, a 17 kDa cytokine, is mainly secreted by activated macrophages [2] and monocytes [3] in response to several inflammatory and immunological stimuli. For example, during bacterial infection, lipopolysaccharide (LPS), a component of gram-negative bacterial cell wall, induces the release of TNF-α, one of numerous endogenous cytokines [4]. TNF-α plays an essential role in the immune system [4-6]; where it is involved in inflammation, tumor necrosis, inhibition of viral replication, and in some cases programmed cell death. At the cellular level, TNF-α regulates multiple signaling pathways, such as apoptosis and NF-kβ activation, through its cell surface receptors, TNF-α receptor type 1 (TNFR1) and TNF-α receptor type II (TNFR2) [7]. For example, TNF-α binding to TNFR1 initiates a series of cellular events, such as activation of a group of kinases which includes mitogen-activated protein kinase kinases (MEKKs), mitogen-activated protein kinases (MAPKs), and inhibitor of nuclear factor-kβ kinase kinases (IKKs). Activation of these kinases leads to the regulation of down stream target gene expression, such as cytokines, chemokines and proteases [7].

Overproduction of inflammatory cytokines, such as TNF-α, has been linked to inflammatory disorders such as Crohn’s disease (CD) and inflammatory bowel disease [8, 9]. Currently, the most effective treatments approved by the FDA for CD are the protein-based TNF-α antagonists such as infliximab and adalimumab [9]. Natural products have also been investigated, due to several potential side effects of these protein-based TNF-α inhibitors. Several small molecule natural products including etanercept, resveratrol, curcumin, and lycorine have been found to reduce TNF-α levels, and may be an alternative approach to the development of small molecule inhibitors to suppress TNF-α signaling [7].

In order to screen large amounts of compounds to identify new inhibitors that block TNF-α secretion, a fast and simple assay format is needed. Currently, the most common available methods for TNF-α measurement are ELISA (Enzyme Linked ImmunoSorbent Assay) and radioisotope labeled immune assay. However, these assays have complicated assay protocols including several wash steps with long incubations and generation of a large amount of radioactive waste, which limits the screen throughput. In this study we have developed two homogenous TNF-α assays using HTRF-based and AlphaLISA-based assay formats. Both assays have been miniaturized into a 1536-well plate format and validated in a quantitative high throughput screening (qHTS) platform [10].

MATERIALS AND METHODS

Cell Line and Culture Conditions

The THP-1 (Human Acute Monocytic Leukemia) cell line was obtained from American Type Culture Collection (ATCC TIB-202; Manassas, VA). THP-1 cells, which origi-
nate from the blood of a boy with acute monocytic leukemia [11], were cultured in RPMI 1640 (ATCC) medium supplemented with 10% fetal bovine serum (FBS, Thermo Scientific HyClone, Logan, UT, USA), 50 U/ml penicillin and 50 μg/ml streptomycin (Invitrogen, CA), and 0.05 mM 2-Mercaptoethanol (Invitrogen). The cell cultures were maintained in a 37°C incubator with 5% CO2 and under a humidified atmosphere.

**Chemical Compounds**

A library of pharmacologically active compounds (LO-PAC), containing 1280 compounds with known pharmacological actives, was purchased from Sigma (St. Louis, MO). Lipopolysaccharides (LPS), dobutamine hydrochloride, ellipticine, histamine dihydrochloride, Bay 11-7085, PD 169316, BTO-1, and IRAK-1/4 Inhibitor I were obtained from Sigma. CCG-2046 was purchased from Tocris Bioscience (Ellisville, MO).

**HTRF-Based TNF-α Assay and qHTS**

The secreted Human TNF-α in the cell culture medium of THP-1 cells was measured using an assay kit (Cisbio Bioassays, Bedford, MA, USA) based on the HTRF format (Fig. 1). HTRF [12, 13] combines standard FRET (fluorescence resonance energy transfer) technology with time-resolved fluorescent measurement, which could eliminate short-lived background fluorescence. For the assay optimization, THP-1 cells suspended in culture medium were dispensed at 2000, 3000 or 4000 cells/5 μL/well in 1536-well white solid plates (Greiner Bio-One North America, Monroe, NC) using a Bioprept dispensing system (Aurora Discovery, CA, USA). Twenty-three nL of LPS, a known TNF-α inducer [4], at final concentration ranging from 0.56 ng/ml to 9.2 μg/ml was transferred to the assay plate by a pintool work station (Kalypsys). The assay plates were incubated at 37°C for 5, 17, or 24 hr, followed by addition of 5 μL mixture of cryptate labeled and XL665 labeled anti-TNFα antibodies. After the assay plates were incubated at room temperature (RT) for 3 hr, the plates were measured by a plate reader in a HTRF detection mode.

The TNF-α antagonist screening was described in Fig. 2. Briefly, THP-1 cells were dispensed at 3000 cells/4 μL/well in 1536-well white solid bottom plates, followed by an addition of 23 nL compound in DMSO solution from LO-PAC library or DMSO only with a pintool work station (Kalypsys). Each compound was screened at 7 final concentrations ranging from 2.9 nM to 46 μM, as the DMSO solutions of compound library was titrated at 1:5 ratio. After a 5 to 10 min incubation, 1 μL LPS in assay medium at 5 μg/mL LPS (final concentration of 1 μg/mL) was dispensed into the assay plates by a Bioprept dispensing system. The assay plates were incubated for 17 hours at 37°C, followed by addition of 5 μL mixtures of cryptate labeled anti-TNFα antibody and XL665-labeled TNF-α antibody. After the assay plates were incubated at RT for 3 hr, the dual fluorescence emissions of 615 and 665 nm with a 320 nm excitation were measured using an Envision plate reader (Perkin Elmer, Shelton, CT). The results were expressed as the ratio of 665nm/615nm emissions. The signal (ratio) was reciprocally reduced with the increase of secreted TNF-α in the medium. There was no detergent in the assay buffer for this TNF-α assay. Thus, the cells in each well were kept intact and only the secreted TNF-α was detected.

**Hit Compounds**

After primary screening, the selected actives were cherry-picked and re-tested for the inhibition of LPS induced TNF-α production in 24 point titrations with final concentration ranging from 6 pM to 46 μM in a HTRF human TNF-α assay. The principle of the assay is shown in Fig. 1. In the absence of TNF-α, there is no FRET between these two labeled antibodies, which produces fluorescent signal at 615 nm (Fig. 1A). When TNF-α is present, these two labeled antibodies are brought into close proximity of each other, which allows FRET to occur between the two fluorophores, europium Cryptate and XL665 (Fig. 1B). This reaction produces a fluorescent signal at 665 nm. The increase of FRET levels is proportional to the concentrations of TNF-α.

![Principle of HTRF-based TNF-α assay](image-url)

**Fig. (1).** Principle of HTRF-based TNF-α assay. The assay was designed using time resolved fluorescence resonance energy transfer (TR-FRET) technology. In this assay, two anti-TNF-α antibodies are labeled with europium Cryptate and XL665, respectively. In the absence of TNF-α, there is no FRET between these two labeled antibodies, which produces fluorescent signal at 615 nm (Fig. 1A). When TNF-α is present, these two labeled antibodies are brought into close proximity of each other, which allows FRET to occur between the two fluorophores, europium Cryptate and XL665 (Fig. 1B). This reaction produces a fluorescent signal at 665 nm. The increase of FRET levels is proportional to the concentrations of TNF-α.
assay using the same protocol as described above except that the 24 point titrations were laid out within one 1536-well plate.

Furthermore, the powder samples of eight compounds confirmed from the above assay were re-ordered from commercial sources and tested in the same assay protocol as described above.

**AlphaLISA-Based TNF-α Assay**

An alternative homogenous TNF-α assay based on PerkinElmer AlphaLISA [14, 15] assay format (Fig. 3) was used to confirm the active compounds identified from the primary screen of HTRF based assay. The cell seeding, compound addition and LPS treatment were the same as described above except the detection of TNF-α was using an AlphaLISA-based assay. Briefly, 1.5 μL of the mixture containing acceptor beads conjugated with anti-TNF-α antibody was added into each well after the assay plates were incubated at 37°C for 17 hr. The assay plates were incubated in the dark at RT for 1 hr, followed by the addition of 1.5 μL of donor bead. After the assay plates were incubated in the dark at RT for another 0.5 to 1 hr, the assay plates were read in the AlphaScreen mode on the Envision plate reader (PerkinElmer).

**Measurement of TNF-α Using ELISA Method**

THP-1 cells were plated at the cell density of 4.8 x 10⁴ in 200 μl culture medium per well in a 96-well plate. Twenty-five μL culture medium with or without compound was added into each well, followed by the addition of LPS at 1 μg/ml final concentration in culture. The final concentrations of the compounds in the wells ranged from 1.6 nM to 30 μM. After 17 hr treatment at 37°C, the cell culture supernatants were removed and measured for human TNF-α using human TNF-
α immunoassay kit (R&D Systems, Minneapolis, MN). Briefly, 200 μL of sample or known standard (0-1000 pg/ml) was added to wells of a microplate which was pre-coated with a monoclonal antibody specific for TNF-α and incubated at RT for 2 hr. After washing away any unbound substances, an enzyme-linked polyclonal anti-TNF-α antibody was added and the plate incubated for 1 hr at RT. Following four washes, a substrate solution was added and incubated for 15-20 min, followed by the addition of a stop solution. The optical density of each well was determined at 450 nm with 570 nm as a reference filter using an EnVision plate reader.

The raw data was normalized to LPS (1 μg/mL, 100%) and assay medium with 0.1% DMSO (basal, 0%). The inhibition curves for each compound were analyzed using the non-linear regression analysis program in GraphPad Prism (Software).

qHTS Data Analysis

Data normalization, correction and fitting of concentration response curves were performed as previously described [16]. Briefly, raw results for each titration point was first normalized relative to the LPS control (1 μg/ml, 0%) and DMSO only wells (basal, 0%), and then corrected by applying a pattern correction algorithm using compound-free control plates (DMSO plates) to minimize the dispense and reading errors. Concentration-response titration points for each compound were fitted to the Hill equation yielding concentrations of half-maximal inhibition (IC50) and maximal response (efficacy) values. Concentration response curves were classified into four major classes using the set of criteria listed in previous studies [17].

Compounds which showed inhibition in both the ratiometric and 665 nm readings, and had potency less than 5 μM and efficacy greater than 50% in the ratiometric reading were considered as active in the HTRF human TNF-α assay. These compounds were further prioritized based on their activity in the cell viability assay after 17 h compound treatment. Twenty-six active compounds that were not apparently cytotoxic (6 times more potent in the HTRF human TNF-α assay than that in the cell viability assay) were cherry-picked for confirmation and follow up studies.

RESULTS

Assay Optimization and Miniaturization of HTRF-Based TNF-α Assay

We have optimized and validated a homogenous HTRF-based TNF-α assay in a 1536-well plate format that can be used to screen compounds to identify potential TNF-α inhibitors (Fig. 1). LPS, a known TNF-α stimulator, induced TNF-α production in a concentration-dependent manner after 17 hr incubation with the THP-1 cells (Fig. 4A). The EC50 of LPS was 0.84 μg/ml, and the maximum induction of TNF-α production by LPS was more than 8-fold of the basal level. To determine the optimal incubation time, the cells were incubated with concentration titrations of LPS for 5 to 24 hr. The EC50s of LPS were 0.70, 0.74 and 0.84 μg/ml for 2000, 3000, and 4000 cells per well, respectively. The signal-to-basal ratios under maximum LPS treatment after 17 hr incubation were 6.9-, 9.1-, and 9.1-fold for the cell density at 2000, 3000, and 4000 cells per well, respectively. Thus, 3000

![Fig. (3). Principle of AlphaLISA-based TNF-α assay. The Alpha donor bead (blue color) is coated with streptavidin which captures the biotinylated anti-TNF-α antibody. The acceptor bead (orange color) is coated with TNF-α specific antibody. When TNF-α is present, the two coated beads are brought into proximity through binding to TNF-α. After excitation by laser at 680 nm, the singlet oxygen released by alpha donor bead travels to the nearby acceptor bead where it causes acceptor bead to emit fluorescence at 615 nm. The increase of AlphaLISA signal is proportional to the concentrations of TNF-α.](image-url)
cells/well was chosen to prevent possible overcrowding of cells at the higher density of 4000 cells/well.

Thus, this assay is simple and robust and is suitable for high throughput screening of compound libraries. It has been miniaturized into the 1536-well plate format to increase screen throughput and to reduce reagents consumption.

### LOPAC Library Screen Using qHTS

The LOPAC library containing 1280 compounds with known pharmacological activities was screened to evaluate the HTRF TNF-α assay. The inhibitory effect of the compounds on TNF-α production was measured in the presence of 1 μg/ml (EC

The compound potencies and efficacies were calculated from the primary results obtained from this LOPAC library screen using the HTRF-based TNF-α assay as it was described in the Methods section. The primary hits were selected as these compounds had IC

The compound potencies and efficacies were calculated from the primary results obtained from this LOPAC library screen using the HTRF-based TNF-α assay as it was described in the Methods section. The primary hits were selected as these compounds had IC

### Confirmation of TNF-α Inhibitors Using an AlphaLISA-Based TNF-α Assay

The 26 cherry-picked compounds were re-tested in the HTRF-based TNF-α assay. The inhibitory activity of LPS-induced TNF-α production was confirmed in 25 of 26 selected compounds (Table 1) and the confirmation rate of was 96%. To eliminate the potential false positives due to the detection method used in the above assay, these 25 compounds were further evaluated in another homogeneous

### Comparison of the Homogenous HTRF-Based Assay with the Traditional ELISA-Based Assay

To further validate the TNF-α inhibitors identified from both the homogenous HTRF-based and the AlphaLISA-based TNF-α assays, eight compounds were selected based on potency and diversity of mechanism of action and purchased from commercial chemical vendors. The inhibitory effect of these compounds on LPS induced TNF-α

Each value is the mean ± SD of the results from two experiments in duplicates.

production in THP-1 cells was determined using a traditional ELISA assay that is the gold standard for cytokine measurement. As shown in Table 2, all eight compounds inhibited LPS induced TNF-α production with IC₅₀s ranging from 10 nM to 1.95 μM. It was notable that the potencies of all the compounds tested in the ELISA-based assay were higher than the potencies obtained from the HTRF-based assay, with IC₅₀ shifts ranging from 2- to 7-fold (Table 2). For example, Bay 11-7085 had higher potency in the ELISA-based assay (IC₅₀, 0.293 μM) than in the HTRF-based assay (IC₅₀, 1.43 μM), with a 4.9-fold IC₅₀ shift (Fig. 5A). The IC₅₀ shifts of CCG-2046 (2.32 μM in the HTRF assay, and 0.66 μM in the ELISA assay) and PD 169316 (2.18 μM in HTRF assay, and 10.6 nM in ELISA assay) were 4-, 5- and 7-fold, respectively. The other four compounds, BTO-1, dobutamine, ellipticine and histamine, had 2 to 3-fold IC₅₀ shifts (Table 2). However, the ranking orders of the compound potencies were comparable between the two assay formats. The IC₅₀ values of these compounds in both the ELISA-based and HTRF-based assays correlated very well with an R² of 0.93. In addition, these eight compounds were also tested in a cell viability assay to evaluate the potential cytotoxicity because the cytotoxic compounds could show the false effect on the reduction of TNF-α production in the cell based assays. We found that all these compounds showed none or weak cytotoxic effect (Table 2). Taken together, these data suggest that the homogenous HTRF-based TNF-α assays can be used to identify small molecule compounds that inhibit TNF-α production.

DISCUSSION

The measurements of cytokine levels in serum and tissues are important to study the immune response, inflammatory disease status and drug responses. Radioimmunoassay (RIA) was first developed to measure the concentration of insulin in plasma [18]. RIA is a sensitive in vitro method that is also applied to measure other antigen and cytokines.
Table 2. Comparison of Potency (µM, IC₅₀) of Commercial Ordered Compounds in ELISA-Based TNF-α, HTRF-Based TNF-α, and Cell Viability Assays

| Compound Name          | ELISA      | HTRF       | Cytotoxicity |
|------------------------|------------|------------|--------------|
| Bay 11-7085            | 0.33 ± 0.15| 1.45 ± 0.11| 7.72         |
| BTO-1                  | 1.95 ± 0.7 | 4.61 ± 0.37| 12.9         |
| CCG-2046               | 0.64 ± 0.09| 2.44 ± 0.002| 8.66        |
| Dobutamine hydrochloride| 0.09 ± 0.05| 0.21 ± 0.02| Inactive     |
| Ellipticine            | 0.44 ± 0.07| 1.38 ± 0.22| 10.9         |

| PD 169316              | 0.01 ± 0.001| 0.07 ± 0.01| 25.9        |

Each value in ELISA and HTRF-based assays is the mean ± SD of the results from two experiments in duplicates. Cell viability assay was performed in duplicates from one experiment.

Fig. (5). Concentration response curves of TNF-α inhibitors in a HTRF-based TNF-α assay (▼) and ELISA-based assay (●). TNF-α level was measured after THP-1 cells were incubated with various concentrations of Bay 11-7085 (A), CCG-2046 (B), IRAK-1/4 inhibitor (C) and PD 169316 (D) in the presence of 1 µg/ml LPS for 17 hr.

Although this assay is sensitive and specific, it requires the use of radioisotope and thus produces the radioactive waste. The RIA assay involves a specific antibody that recognizes the radioactive labeled cytokine tracer and multiple assay steps including extensive wash cycles. In the 1970s, ELISA [19, 20], also known as an enzyme immunoassay (EIA), was introduced, where the specific antigen (cytokine)-antibody reaction was measured using colorimetric readout instead of a radioactive signal. In the ELISA method, two specific antibodies are usually used with one antibody linked to a reporter enzyme. After several extensive reagent additions and plate washes, the substrate is added and a color change re-
results from an enzyme reaction due to the binding of cytokine to enzyme linked antibody. The intensity of the color produced is proportional to the levels of the cytokine such as TNF-α. The ELISA method is widely utilized in biomedical research because it doesn’t use radioactivity and is a standard method used in immunological experiments to detect cytokines.

For the large scale compound library screening, the throughput using ELISA is low and the assay procedure is complicated because the ELISA assay requires extensive wash cycles and antibody pre-coated plates. Therefore, the homogenous and simple assay method for measurement of cytokine level is needed for compound library screens. The assay should be miniaturized into high plate density formats such as 384-well and 1536-well plates as well as being sensitive to compounds. We have optimized the HTRF-based and AlphaLISA-based TNF-α assay into the homogenous format. The detection reagents are directly added into the wells of the assay plate treated with stimulant and compounds without involving the medium transferring that is needed in the original assay protocol. We found that the activities of TNF-α inhibitors identified in these homogenous assays were well correlated with those obtained from the ELISA-based assay.

Compared to the traditional ELISA method, these assays can be easily miniaturized into a 1536-well plate format and are homogeneous, and no plate wash or supernatant transfer steps. The frequent plate incubations needed in the ELISA assay was reduced significantly. Furthermore, the ratiometric readout from the dual emissions (665 and 615 nm) used in the HTRF-based TNF-α assay minimizes the well-to-well and plate-to-plate variations that are caused by subtle differences in cell numbers and dispensing error.

We also found that the potencies of compounds obtained in the HTRF-based TNF-α assay were slightly lower than those measured in the ELISA method. Among these compounds tested, a 2- to 7-fold shift of activities was observed. This could be due to the fact that ELISA can have increased sensitivity because it is a plate based, and fixed assay system which increases the capture ability of the antibody. Also, the many wash steps in the ELISA protocol will remove any non-specific binding of the antibody. Finally, the antibodies used in the different assays may have different affinities for the antigen, resulting in different sensitivity of the assay. However, the potency ranking orders of compounds tested in ELISA and homogenous assay formats were similar. Therefore, both the HTRF-based and AlphaLISA-based TNF-α assays are still preferable for high throughput screening of large compound collection. The ELISA based TNF-α assay can be used as a confirmation assay to validate the active compounds identified from the primary screens.

Beta-adrenergic agonists are known to suppress LPS-induced TNF-α production [21]. After a beta-adrenergic agonist binds to its receptor, adenylyl cyclase (AC) is activated by Gα protein which leads to an increase of intracellular cAMP. It has been shown that the increased cAMP stimulated by beta-adrenergic agonists can reduce the TNF-α mRNA levels [22]. Consistent with previous reports, we found more than a dozen beta adrenergic agonists including norepinephrine, epinephrine, dobutamine and fenoterol from the LOPAC library with an inhibitory effect on TNF-α production. In addition, we also found that histamine inhibited LPS-induced TNF-α production in THP-1 cells, which is consistent with a previous report that histamine suppressed the LPS-induced synthesis of TNF-α in peripheral blood mononuclear cells [23]. The inhibition of histamine on TNF-α production is caused by a similar mechanism as the beta adrenergic agonists. Histamine binds to and activates the histamine type 2 (H2) receptor that resulting in activation of Gα protein, and AC and thus increasing intracellular cAMP [23].

The binding of TNF-α to its receptor initiates the signaling cascade resulting in activation of the NF-κB and MAP kinase signaling pathways [7]. Previous studies reported that Bay 11-7082 [24], Bay 11-7085 [25], N-p-tosyl-L-phenylalanine chloromethyl ketone [26], IRAK-1/4 inhibitor I [27], and parthenolide [28] had inhibitory effects on the NF-κB signaling pathway. PD 169316 [29] was reported to inhibit the p38 MAP kinase. These compounds were found in our LOPAC library screen to inhibit the LPS induced TNF-α production in THP-1 cells, suggesting that the inhibition of NF-κB and MAP kinase signaling pathways by these compounds could be a result of the inhibition of TNF-α production.

BTO-1, CCG-2046, and ellipticine were identified as inhibitors of LPS induced TNF-α production from this LOPAC library screen. BTO-1 is a polo-like kinase I inhibitor, which inhibits spindle assembly, mitotic entry and chromosome segregation [30]. Ellipticine, an alkaloid derived from the leaves of the evergreen tree, is known as a DNA intercalating agent [31] and an inhibitor of the enzyme topoisomerase II [32]. However, the roles of these compounds and the mechanism of action on LPS-induced TNF-α production still need further investigation. These compounds might be useful as research tools in the fields of inflammation and immunology.

In summary, we have optimized and validated two homogenous TNF-α assays using HTRF and AlphaLISA assay formats. Both assays were miniaturized into 1536-well plates in a qHTS format. From a test screen of the LOPAC library, we have identified twenty-five TNF-α inhibitors. All these compounds showed reproducible activities in these two assays. Eight out of the 25 compounds were further evaluated in the traditional ELISA based TNF-α assay. The IC50 values of these compounds measured from the homogenous HTRF-based TNF-α assay correlated very well with those determined in the TNF-α ELISA assay. Out of the 25 compounds, 15 are beta adrenergic receptor agonists, five are known inhibitors of the NF-κB pathway, and one compound is a histamine H2 receptor agonist. The identification of these 21 known inhibitors further demonstrated that these two homogenous TNF-α assays reported here are valid for compound screening. We also found four compounds including BTO-1, CCG-2046, ellipticine, and PD 169316 as new inhibitors of LPS induced TNF-α production. Taken together, our results indicated that these homogenous TNF-α assays can be used to quickly and efficiently screen large compound collections and to identify compounds that can potentially inhibit TNF-α production.
