Abstract. If interpreted in terms of decaying dark matter, the steep rise in the positron fraction of cosmic rays above 10 GeV, as observed by the PAMELA experiment, suggests an underlying production mechanism that favors leptonic channels. We consider a scenario where a portion of the dark matter is made of the gauginos of an unbroken hidden-sector U(1)X, which interact with the visible sector only through a tiny kinetic mixing. The second component of the dark matter is made of neutralinos, and depending on the mass spectrum, either the lightest neutralino or the hidden gaugino becomes unstable and subject to decay. We analyze the cosmic rays, namely the contributions to the positron, the extragalactic gamma-ray and the antiproton flux, which potentially result from these decays and demonstrate that the production of antiprotons can be naturally suppressed. Furthermore, we briefly discuss the apparent double-peak structure of theATIC data in light of cascade-decaying hidden gauginos, as well as possible signatures at Fermi.

Keywords: cosmic ray theory, supersymmetry and cosmology, dark matter theory

1 Introduction

The PAMELA collaboration has recently reported a measurement of the positron fraction \([1]\) which shows a significant excess at high energies compared to the expectations from spallation of cosmic rays on the interstellar medium \([2]\). This result confirms hints at an excess in the positron fraction reported in the past by several experiments: HEAT 94/95/00 \([3]\), CAPRICE94 \([4]\) and AMS-01 \([5]\). More importantly, the PAMELA collaboration has provided an accurate measurement of the energy spectrum of the positron fraction, revealing a steep rise between 7 and 100 GeV, possibly extending to even higher energies.

The excess in the positron fraction has been interpreted as an indication for the annihilation \([6-9]\) or the decay \([10-12]\) of dark matter particles. If interpreted as dark matter annihilations, the dark matter particles must annihilate into \(W, Z, e, \mu, \tau\) for any dark matter mass, or into \(q, b, t, h\) for a multi-TeV dark matter mass. In both cases one needs large boost factors, e.g. from dark matter substructures, since the required annihilation rates are much larger than the cross-section suggested by cosmology, \(\langle \sigma v \rangle \approx 3 \times 10^{-26} \text{ cm}^3 \text{ s}\) \([13]\), would lead one to expect. On the other hand, if interpreted as dark matter decay, the dark matter particles must have a mass larger than \(\sim 300\) GeV, a lifetime around \(10^{26}\) s, and the decay must proceed preferentially into charged leptons of the first and second generation \([14]\).

The properties of the dark matter particles are also subject to constraints from the diffuse gamma-ray flux as measured by the EGRET instrument \([15]\), from H.E.S.S. and VERITAS observations of dwarf galaxies \([16]\), and the antiproton flux, as measured by PAMELA \([17]\), BESS95 \([18]\), BESS95/97 \([19]\), CAPRICE94 \([20]\), CAPRICE98 \([21]\) and IMAX \([22]\). More concretely, the good agreement of the theoretical predictions for the antiproton flux with the measurements suggests that the dark matter particles annihilate or decay mostly into leptons. Moreover, if one additionally takes into account the spectral feature in the total electron+positron flux observed by the ATIC experiment \([23]\), dark matter particle masses
above 1 TeV are suggested.\footnote{For the combined electron+positron flux, we use results from measurements that have been undertaken by ATIC, HEAT94/95 [24], PPB-BETS [25], H.E.S.S. [26], BETS [27], CAPRICE94 [4] and SANRIKU [28].} Although the interpretation of the positron excess in terms of dark matter is very suggestive, it should be borne in mind that nearby astrophysical sources such as pulsars might produce sizable positron fluxes in the energy range explored by PAMELA [29].

In this paper we will discuss the cosmic-ray signatures of supersymmetric scenarios with a gaugino of an unbroken hidden-sector U(1) gauge group which interacts with the visible sector only via a tiny kinetic mixing [30]. We will speculate that the tiny kinetic mixing induces the decay of the dark matter particles into lighter supersymmetric particles and positrons, thus providing a potential explanation of the excess observed by PAMELA. Assuming exact $R$-parity conservation, two possibilities may arise. First, we will study the case that the hidden gaugino mass is smaller than the lightest neutralino mass. We will show that the neutralino mostly decays into two charged leptons and the hidden gaugino. The hard positrons produced in the decay can then potentially explain the steep rise in the positron fraction observed by PAMELA and the absence of an excess in the antiproton flux. Secondly, we will study the case that the lightest neutralino mass is smaller than the hidden gaugino mass. If this is the case, it is the hidden gaugino which decays into the lightest neutralino, either directly or in a cascade decay, when there are supersymmetric particles with masses between the hidden gaugino mass and the lightest neutralino mass. Either particle could be the dominant component of dark matter. However, we will focus in this work on the possibility that the dominant component of dark matter is the lightest neutralino, which may allow direct dark matter detection.

In section 2 we will briefly review the main features and possible origins of scenarios with a hidden Abelian gauge group and kinetic mixing. In section 3 we will review the procedure to calculate the gamma-ray, positron and antiproton fluxes at Earth from dark matter decay. In section 4 we will present our results for the decaying neutralino and the decaying hidden gaugino case. Lastly, in section 5 we will present our conclusions.

2 Model

Many extensions of the Minimal Supersymmetric Standard Model (MSSM) contemplate the possibility of a hidden sector, consisting of superfields which are singlets under the Standard Model gauge group. Hidden-sector superfields usually couple very weakly to our observable sector, thus constituting a very natural arena for finding dark matter candidates. We consider an extension of the MSSM by a hidden Abelian gauge group U(1)$_X$ (for details about the model see ref. [30]). This gauge group remains unbroken at low energies and couples to the MSSM only through a tiny kinetic mixing, $\chi$, with the hypercharge U(1)$_Y$ [31]:

$$SU(3)_c \times SU(2) \times U(1)_Y \times \frac{U(1)_X}{\text{kin. mixing } \chi}.$$

We assume that all matter states charged under U(1)$_X$ are heavy and negligible. As a consequence the U(1)$_X$ gauge boson completely decouples from the observable sector. However, as shown in ref. [30], a non-zero mass-mixing of the order of $\delta M \sim O(\chi \cdot M_X)$ between hidden gaugino and bino generally remains. More precisely, in the basis where the kinetic terms are
canonical, the extended $(5 \times 5)$ neutralino mass matrix reads, to lowest order in $\chi$,\hfill (2.2)
\begin{equation}
\mathcal{M}_N = \begin{pmatrix}
M_X & \delta M & 0 & 0 & 0 \\
\delta M & M_1 & 0 & -M_Z c_\beta s_W & M_Z s_\beta s_W \\
0 & 0 & M_2 & M_Z c_\beta c_W & -M_Z s_\beta c_W \\
0 & -M_Z c_\beta s_W & M_Z c_\beta c_W & 0 & -\mu \\
0 & M_Z s_\beta s_W & -M_Z s_\beta c_W & -\mu & 0
\end{pmatrix}.
\end{equation}

Here, $\mu$ denotes the MSSM $\mu$-term, $M_Z$ the mass of the $Z^0$ gauge boson, $M_1$ and $M_2$ the bino and wino masses, respectively, $s_W$ the sine of the Weinberg angle and $c_\beta$ is related to the ratio of the two Higgs VEVs.

Below, we will concentrate on the case where the lightest supersymmetric particle in the visible sector is a bino-like neutralino $\chi^0_1$. Then, depending on the masses of the hidden gaugino and of the neutralino, one of the two particles becomes unstable with a lifetime that is roughly given by\hfill (2.3)
\begin{equation}
\tau_{X,\chi^0_1} \sim \mathcal{O} \left(10^{-2} - 10 \right) \times 10^{26} \text{s} \cdot \left( \frac{M_{X,\chi^0_1}}{100 \text{ GeV}} \right)^{-1} \left( \frac{\theta}{10^{-24}} \right)^{-2},
\end{equation}
where we made use of the mixing angle $\theta \simeq \delta M / |M_{\chi^0_1}| - M_X | \sim \mathcal{O}(\chi)$. The exact prefactor depends on the dominant decay modes and on the mass spectrum of the supersymmetric particles. However, it is apparent that a lifetime around $10^{26}$ s, as required to fit the PAMELA excess with decaying dark matter particles, implies an extremely small mixing of the order of $\chi \sim 10^{-24}$. Note that the mixing must be somewhat larger when the decaying particle is only a subdominant component of the dark matter, but an upper bound of roughly $\sim 10^{-20}$ holds from the requirement that the particle relic abundance has not already decayed.

The thermal production of hidden gauginos by oscillations between bino and hidden gaugino, which generally takes place in the primeval MSSM plasma, is irrelevant for the mixing parameters that we are looking at [30]. However, the hidden gaugino may be produced non-thermally, e.g. in the decay of a heavy gravitino, or it may be a thermal relic of the hidden sector [32]. In the latter case one requires additional particles that are charged under the hidden $U(1)_X$ with masses around $M_X$, however. For simplicity, we will assume throughout this work that the lightest neutralino in the visible sector has the right energy density to make up the dominant part of the observed dark matter, whereas the abundance of the hidden gaugino is always subdominant, $\rho_X \ll \rho_{\chi^0_1} \simeq \rho_{\text{DM}}$.

The actual mass scale of the hidden gaugino depends on how the breaking of supersymmetry is mediated to the visible sector and the hidden $U(1)_X$. If the soft masses $M_{\text{soft}}$ in the visible sector arise from gauge mediation, whereas $U(1)_X$ couples to the supersymmetry-breaking sector only gravitationally, the predicted mass hierarchy is $M_{\text{soft}} \gg m_{3/2} \sim M_X$, where $m_{3/2}$ denotes the mass of the gravitino. In this scenario the lightest neutralino cannot be dark matter, because it would decay into the gravitino in the early Universe. However, if we suppose gravity mediation to the visible sector and anomaly mediation [33] to the $U(1)_X$, one expects $M_{\text{soft}} \sim m_{3/2} \gg M_X$. If the soft masses of both the visible sector and the $U(1)_X$ arise from gravity mediation, one in general expects that all masses are of the same order $M_{\text{soft}} \sim m_{3/2} \sim M_X$. Below we will assume that the gravitino is heavy enough to have no impact on the decay modes, $m_{3/2} > \max(M_X, M_{\chi^0_1})$.

Additional hidden sector $U(1)$ gauge factors are a generic feature of string compactifications. For example, in the “mini-landscape” of orbifold compactifications of the heterotic
string [34] one encounters, at the compactification scale, a breaking of the gauge symmetry to a theory involving many hidden U(1)s, e.g. $E_8 \times E_8 \rightarrow G_{\text{SM}} \times U(1)^4 \times \left( \text{SO}(8) \times \text{SU}(2) \times U(1)^3 \right)$ and the like. Similarly, type II compactifications generically invoke hidden sector U(1)s, often also for global consistency requirements. Some of these hidden U(1)s may remain unbroken down to very small scales [35].

Kinetic mixing is generated by the exchange of heavy messengers that couple both to the hypercharge U(1)$_Y$ as well as to the hidden U(1)$_X$. Correspondingly, it is loop-suppressed, $\chi = g_Y g_X C / (16\pi^2)$, where $g_Y$ and $g_X$ are the Abelian gauge couplings and $C$ is a dimensionless constant. In field-theoretic setups, the latter is naturally of order one [31] and thus way too large for our purposes. However, it can be much smaller if there are additional gauge or global symmetries (cf. refs. [30, 36]). Moreover, in models arising from string compactifications rather small mixings seem to be generic [35, 37–39]. In the context of compactifications of the heterotic string, the size of the mixing has been estimated as [37]

$$\chi \sim \frac{g_Y g_X \Delta m}{16\pi^2 M_P},$$

(2.4)

where $\Delta m \ll M_P$ is the mass splitting in the messenger sector and $M_P$ is the Planck scale. Indeed, the mixing is quite small in this case (e.g. $\chi \sim 10^{-16}$, if $\Delta m$ is associated with gauge mediated supersymmetry breaking, $\Delta m \sim 100 \text{TeV}$), but still too large for our purposes. However, a sufficiently strong suppression of the coupling could be achieved in models with multiple hidden U(1)s [30].

In compactifications of type-II string theories, where the hidden U(1)s arise via D-branes in the (extra-dimensional) bulk that have no intersection with the branes responsible for the visible sector, one has to distinguish two cases.

i) In large volume scenarios, where the hidden D3-branes and the branes supporting hypercharge are located at generic positions in some Calabi-Yau, kinetic mixing is suppressed by the large volume $V_6$ of the extra dimensions [39],

$$\chi \simeq \frac{g_Y g_X}{16\pi^2} \left( V_6 M_s^6 \right)^{-2/3},$$

(2.5)

where $M_s$ is the string scale, which is related to the Planck scale via $M_s \sim g_s M_P / \sqrt{V_6 M_s^6}$, where $g_s$ is the string coupling. We thus see that we may obtain a kinetic mixing of order $10^{-24}$, if we assume $V_6 M_s^6 \sim 10^{32}$, corresponding to a string scale of order $M_s \sim \text{TeV}$.

However, this case is problematic because the mass of the gravitino is of the order of meV [40], with impact on the stability of supersymmetric dark matter candidates like the neutralino or hidden gaugino.

ii) In scenarios with significant warping, such as KKLT [41], the standard model stack of branes, notably the brane featuring the hypercharge U(1), is placed at a special position — at the tip of a warped throat — while the hidden brane is separated from it by a distance $d$ along the throat. In this case kinetic mixing may be exponentially suppressed [39] like

$$\chi \sim \frac{g_Y g_X}{16\pi^2} e^{-md},$$

(2.6)

reminiscent of a “Yukawa-type” interaction. In fact, in warped compactifications the closed string fields that mediate the kinetic mixing, notably the NS-NS $B$ form and the R-R $C$ form fields, acquire masses,

$$m \sim n M_s / \left( V_3 M_s^3 \right),$$

(2.7)
Neutralino / hidden gaugino decay modes

| $M_{\chi^0_1} > M_X$ | $M_{\chi^0_1} < M_X$ |
|------------------------|------------------------|
| $\chi^0_1 \rightarrow \begin{cases} f\tilde{f}_{L/R} \rightarrow f\tilde{f}X \\ Xh^0 \\ XZ^0 \end{cases}$ | $X \rightarrow \begin{cases} f\tilde{f}^0_{L/R} \rightarrow f\tilde{f}\chi^0_1 \\ \chi^0_i h^0 \\ \chi^0_i Z^0 \\ \chi^\pm_j W^\mp \end{cases}$ |

Table 1. Dominant decay modes. Depending on the masses of the hidden gaugino, $M_X$, and the lightest neutralino, $M_{\chi^0_1}$, one of the two particles becomes unstable with a lifetime roughly given by eq. (2.3). Since the three-body decay into fermion pairs $ff$ is mainly mediated by virtual sfermions, $\tilde{f}^*$, we show this explicitly. Furthermore, when a sfermion is lighter than the decaying particle, the corresponding three-body decay crosses over to a cascade decay. The subsequent decay and fragmentation of the Higgs and gauge bosons, charginos and neutralinos is not shown. Note that the letter $f$ represents any lepton or quark.

for some integer $n$, from the vacuum expectation values of their three-form field strengths, $H_3 = dB_2$, $F_3 = dC_2$, which are threading three-cycles of volume $V_3$ and cause the warping. Therefore, we conclude that no strong fine-tuning is required to obtain a tiny kinetic mixing in a KKLT-like scenario. Indeed, the estimate (2.6) yields the desired small value $\chi \sim 10^{-24}$ for $md \sim 48$.

As mentioned above, depending on the mass spectrum of the supersymmetric particles, either the lightest neutralino, $\chi^0_1$, or the hidden gaugino, $X$, becomes unstable. The relevant decay modes are shown in table 1. These decays may be detectable as anomalous contributions to the cosmic-ray fluxes observed at Earth. We will discuss this in some detail in the next section.

3 Propagation models

The decay of dark matter particles induced by the kinetic mixing discussed above will generate potentially sizable numbers of Standard Model particles which may be detectable in cosmic-ray experiments if the dark matter decay rate is high enough. In the following, we will consider the cosmic-ray signatures resulting from the decay of neutralinos and hidden gauginos in three different channels, namely gamma rays, positrons and antiprotons. Interestingly, in all of these channels, experiments are now reaching sensitivities to dark matter lifetimes of the order of $10^{26}$ s.

Gamma rays. Photons from the decay of GeV — TeV mass dark matter particles will manifest themselves as an anomalous contribution to the diffuse extragalactic gamma-ray background. More specifically, there are two distinct contributions to the diffuse gamma-ray flux from dark matter decay. There is an anisotropic component from the decay of dark matter particles in the Milky Way halo, as well as an isotropic diffuse emission from dark matter decaying at cosmological distances. The latter contribution is red-shifted due to the

---

---
expansion of the Universe. Thus, for a dark matter mass \( m_{\text{DM}} \) and a dark matter lifetime of \( \tau_{\text{DM}} \), the gamma-ray flux will be given by the sum \[ (3.1) \]

\[
\left[ \frac{E^2 \, dJ}{dE} \right]_{\text{DM}} = \left[ \frac{E^2 \, dJ}{dE} \right]_{\text{halo}} + \left[ \frac{E^2 \, dJ}{dE} \right]_{\text{extra}},
\]

where the halo component is given by

\[
\left[ \frac{E^2 \, dJ}{dE} \right]_{\text{halo}} = \frac{2E^2}{m_{\text{DM}}} \frac{dN_\gamma}{dE} \frac{1}{8\pi \tau_{\text{DM}}} \int_{\text{los}} \rho_{\text{DM}}(\vec{r}) d\vec{r},
\]

\[ (3.2) \]

in which \( \rho_{\text{DM}} \) is the dark matter halo profile, which in the following we assume to be a Navarro-Frenk-White (NFW) \[ (44) \] profile for definiteness. The results will have only a slight dependence on the particular choice of halo profile. \( dN_\gamma/dE \) denotes the energy spectrum of photons from dark matter decay. The integration extends along the line of sight (los), yielding an angular dependence of the signal. For our results, we will average the anisotropic halo contribution over the whole sky excluding a band of \( \pm 10^\circ \) around the Galactic disk.

The extragalactic component is given by

\[
\left[ \frac{E^2 \, dJ}{dE} \right]_{\text{extra}} = \frac{2E^2}{m_{\text{DM}}} C_\gamma \int_1^\infty dy \frac{dN_\gamma}{dE} \frac{y^{-3/2}}{\sqrt{1 + \Omega_\Lambda/\Omega_M y^{-3}}},
\]

\[ (3.3) \]

with the coefficient

\[
C_\gamma = \frac{\Omega_{\text{DM}} \rho_c}{8\pi \tau_{\text{DM}} H_0 \Omega_M^{1/2}},
\]

\[ (3.4) \]

The integration is over the red-shift \( z \), with \( y = z + 1 \). In these expressions, \( \Omega_\Lambda \simeq 3\Omega_M \), \( \Omega_M \simeq 0.24 \) and \( \Omega_{\text{DM}} \simeq 0.20 \) are the vacuum, matter and dark matter density parameters, respectively, while \( H_0 = 70.1 \text{km s}^{-1} \text{Mpc}^{-1} \) is the present value of the Hubble parameter and \( \rho_c \) is the critical density. One finds that the halo component is dominant, although both contributions are of the same order. For the background to the dark matter signal from conventional astrophysical sources, we will assume a power law spectrum that fits the data points below 1 GeV,

\[
\left[ \frac{E^2 \, dJ}{dE} \right]_{\text{background}} = 6.8 \times 10^{-7} E^{-0.32} \text{ GeV (cm}^2 \text{ str s)}^{-1}.
\]

\[ (3.5) \]

**Antimatter propagation.** At the energies of interest here, only antiparticles created within the Milky Way’s dark matter halo will be of importance. Antimatter propagation in the Galaxy is a fairly complicated process due to diffusion, energy loss and annihilation effects. It is commonly described using a stationary two-zone diffusion model with cylindrical boundary conditions \[ (45) \]. Under this approximation, the number density of antiparticles per unit kinetic energy, \( f(T, \vec{r}, t) \), satisfies the following transport equation, which applies for both positrons and antiprotons:

\[
\frac{\partial f}{\partial t} = \nabla \cdot [K(T, \vec{r}) \nabla f] + \frac{\partial}{\partial T} [b(T, \vec{r}) f] - \nabla \cdot \left[ \vec{V}_c(\vec{r}) f \right] - 2h\delta(z)\Gamma_{\text{ann}} f + Q(T, \vec{r}).
\]

\[ (3.6) \]

We assume free escape conditions for the solution \( f(T, \vec{r}, t) \) at the boundary of the diffusion zone, which is approximated by a cylinder with half-height \( L = 1 - 15 \text{kpc} \) and radius \( R = 20 \text{kpc} \), and solve the equation for the steady-state case, where \( \partial f / \partial t = 0 \).
The first term on the right-hand side of the transport equation is the diffusion term, which accounts for the propagation through the tangled Galactic magnetic field. The diffusion coefficient $K(T, \vec{r})$ is assumed to be constant throughout the diffusion zone and is parameterized by:

$$K(T) = K_0 \beta \mathcal{R}^\delta,$$

where $\beta = \frac{v}{c}$ is the velocity in units of the speed of light $c$, and $\mathcal{R}$ is the rigidity of the particle, which is defined as the momentum in GeV per unit charge, $\mathcal{R} \equiv p[\text{GeV}]/Z$. The normalization $K_0$ and the spectral index $\delta$ of the diffusion coefficient are related to the properties of the interstellar medium and can be determined from flux measurements of other cosmic-ray species, mainly from the Boron-to-Carbon (B/C) ratio [46]. The second term accounts for energy losses due to inverse Compton scattering on starlight or the cosmic microwave background, synchrotron radiation and ionization. The third term is the convection term, which accounts for the drift of charged particles away from the disk induced by the Milky Way’s Galactic wind. It has axial direction and is also assumed to be constant inside the diffusion region: $\vec{V}_c(\vec{r}) = V_c \text{sign}(z) \hat{k}$. The fourth term accounts for antimatter annihilation with rate $\Gamma_{\text{ann}}$, when it interacts with ordinary matter in the Galactic disk, which is assumed to be an “infinitely” thin disk with half-height $h = 100$ pc. Note that, although this term is completely negligible in the case of positrons, it can have a rather small but noticeable effect on the number density of antiprotons. Lastly, $Q(T, \vec{r})$ is the source term of positrons or antiprotons which is given by

$$Q(E, \vec{r}) = \frac{\rho_{\text{DM}}(\vec{r})}{m_{\text{DM}}\tau_{\text{DM}}} \frac{dN}{dE},$$

where $\frac{dN}{dE}$ is the energy spectrum of antiparticles created via the decay of dark matter particles. In the transport equation, reacceleration effects and non-annihilating interactions of antimatter in the Galactic disk have been neglected.

The solution of the transport equation at the Solar System, $r = r_\odot, z = 0$, can be formally expressed by the convolution

$$f(T) = \frac{1}{m_{\text{DM}}\tau_{\text{DM}}} \int_0^{T_{\text{max}}} dT' G(T, T') \frac{dN}{dT'},$$

where $T_{\text{max}} = m_{\text{DM}}$ for the case of the positrons and $T_{\text{max}} = m_{\text{DM}} - m_p$ for the antiprotons. The solution is thus factorized into two parts. The first part, given by the Green’s function $G(T, T')$, encodes all of the information about the astrophysics (such as the details of the halo profile and the propagation of antiparticles in the Galaxy). The remaining part depends exclusively on the nature and properties of the decaying dark matter particles, namely the mass, the lifetime and the energy spectrum of antiparticles produced in the decay.

We will consider the dark matter lifetime to be a free parameter that is constrained by requiring a qualitatively good agreement of the predicted positron fraction with the PAMELA results. Therefore, the only uncertainties in the computation of the antimatter fluxes stem from the determination of the Green’s function, e.g. from the uncertainties in the propagation parameters and the halo profile. As it turns out, the uncertainties in the precise shape of the halo profile are not crucial for the determination of the primary antimatter fluxes, since the Earth receives mostly antimatter created within a few kpc from the Sun, where the different halo profiles are very similar. On the other hand, the uncertainties in the propagation parameters can substantially change the predictions for the antimatter fluxes, even by as much as two orders of magnitude for the antiproton flux. The reason for this
Table 2. Astrophysical parameters compatible with the B/C ratio that yield the minimum (M2), median (MED) and maximal (M1) flux of positrons.

| Model | $\delta$ | $K_0$ (kpc$^2$/Myr) | $L$ (kpc) |
|-------|---------|---------------------|----------|
| M2    | 0.55    | 0.00595             | 1        |
| MED   | 0.70    | 0.0112              | 4        |
| M1    | 0.46    | 0.0765              | 15       |

large uncertainty is a correlation among the diffusion parameters and the size of the diffusion zone. The ranges of the astrophysical parameters that are consistent with the B/C ratio and that produce the maximal, median and minimal positron and antiproton fluxes are listed in tables 2 and 3 [47, 48].

Positrons and antiprotons have different properties regarding their propagation, and their respective transport equations can be approximated by different limits of eq. (3.6). By exploiting the cylindrical symmetry of the problem, it is then possible to find semi-analytical solutions to the transport equation in each case. Approximate interpolating functions for the Green’s function can be found in ref. [10].

Positron Flux. For the case of the positrons, Galactic convection and annihilations in the disk can be neglected in the transport equation, which is then simplified to:

$$\nabla \cdot [K(T, r) \nabla f_{e^+}] + \frac{\partial}{\partial T}[b(T, r)f_{e^+}] + Q(T, r) = 0 ,$$

where the rate of energy loss, $b(T, r)$, is assumed to be a spatially constant function parameterized by $b(T) = \frac{T^2}{2\tau_E}$, with $T_0 = 1$ GeV and $\tau_E = 10^{16}$ s.

The solution to this equation is formally given by the convolution eq. (3.9). The explicit form of the Green’s function is [8]

$$G_{e^+}(T, T') = \sum_{n,m=1}^{\infty} B_{nm}(T, T') J_0 \left( \frac{\zeta_n r}{R} \right) \sin \left( \frac{m\pi}{2} \right),$$

where $J_0$ is the zeroth-order Bessel function of the first kind, whose successive zeros are denoted by $\zeta_n$. On the other hand,

$$B_{nm}(T, T') = \frac{\tau_E T_0}{T^2} C_{nm} \times \exp \left\{ \left( \frac{\zeta_n^2 R^2}{2 L^2} + \frac{m^2 \pi^2}{4L^2} \right) \frac{K_0 \tau_E}{\delta - 1} \left[ \left( \frac{T}{T_0} \right)^{\delta - 1} - \left( \frac{T'}{T_0} \right)^{\delta - 1} \right] \right\} ,$$

with

$$C_{nm} = \frac{2}{J_1^2(\zeta_n) R^2 L} \int_0^R r' dr' \int_{-L}^L dz' \rho(r') J_0 \left( \frac{\zeta_n r'}{R} \right) \sin \left[ \frac{m\pi}{2L}(L - z') \right],$$

where $J_1$ is the first-order Bessel function.

The interstellar positron flux from dark matter decay is finally given by

$$\Phi_{e^+}^{\text{prim}}(T) = \frac{c}{4\pi \rho_{DM} \tau_{DM}} \int_0^{\rho_{DM}} d\rho G_{e^+}(T, T') \frac{dN_{e^+}(T')}{dT}. \quad (3.14)$$

$^3$In most cases, the propagated positron spectrum only depends mildly on the model that is actually used. For a comparison between different propagation models that feature smaller values of $\delta$ than the ones used in this paper, see e.g. ref. [49].
Table 3. Astrophysical parameters compatible with the B/C ratio that yield the minimal (MIN), median (MED) and maximal (MAX) flux of antiprotons.

The dependence of the positron flux on the diffusion model is mostly important at low energies, where the signal lies well below the background.

Rather than measuring the positron flux, most experiments measure the positron fraction, $\Phi_{e^+}/(\Phi_{e^-} + \Phi_{e^+})$, since most sources of systematic errors, such as detector acceptance or trigger efficiency, cancel out when computing the ratio of particle fluxes. The background to the positron flux from dark matter decay will be constituted by a secondary positron flux originating from the collision of primary protons and other nuclei on the interstellar medium.

For the background fluxes of primary and secondary electrons, as well as secondary positrons, we use the parameterizations obtained in ref. [7] from the GALPROP numerical code for cosmic-ray propagation [2]. We leave the normalization of the primary electron flux as a free parameter to be fitted in order to match the observations of the positron fraction.

**Antiproton flux.** The general transport equation, eq. (3.6), can be simplified by taking into account that energy losses are negligible for antiprotons. Therefore, the transport equation for the antiproton density, $f_{\bar{p}}(T, \vec{r}, t)$, is then given by:

$$0 = \frac{\partial f_{\bar{p}}}{\partial t} = \nabla \cdot \left( K(T, \vec{r}) \nabla f_{\bar{p}} \right) - \nabla \cdot \left( \vec{V}_c(\vec{r}) f_{\bar{p}} \right) - 2h\delta(z)\Gamma_{\text{ann}} f_{\bar{p}} + Q(T, \vec{r}) ,$$

(3.15)

where the annihilation rate, $\Gamma_{\text{ann}}$, is determined by the Galactic Hydrogen and Helium densities and the proton-antiproton scattering cross-section, for which we use the parameterization by Tan and Ng [50].

Analogously to the positron case, the solution to the transport equation can be expressed as a convolution of the form eq. (3.9). The analytic expression for the Green’s function reads [51]:

$$G_{\bar{p}}(T, T') = \sum_{i=1}^{\infty} \exp \left( -\frac{V_c L}{2K(T)} \right) \times \frac{y_i(T)}{A_i(T)\sinh(S_i(T)L/2)} J_0 \left( \frac{r_{\bar{p}}}{R} \right) \delta(T - T') ,$$

(3.16)

where

$$y_i(T) = \frac{4}{J_1^2(\zeta_i)R^2} \int_0^R r' \, dr' \int_0^{L_i} dz' \exp \left( -\frac{V_c(L - z')}{2K(T)} \right) \sinh \left( \frac{S_i(L - z')}{2} \right) \rho(r') ,$$

(3.17)

and

$$A_i(T) = 2h\Gamma_{\text{ann}}(T) + V_c + kS_i(T)\coth \frac{S_i(T)L}{2} ,$$

(3.18)

$$S_i(T) = \sqrt{\frac{V_c^2}{K(T)^2} + \frac{4\zeta_i^2}{R^2}} .$$

(3.19)
The interstellar antiproton flux is then given by

$$\Phi_{\bar{p}}^{IS}(T) = \frac{v_{\bar{p}}(T)}{4\pi m_{DM} T_{DM}} \int_{0}^{m_{DM} - m_{p}} dT' G_{\bar{p}}(T, T') \frac{dN_{\bar{p}}(T')}{dT'},$$

(3.20)

where $v_{\bar{p}}(T)$ is the antiproton velocity. However, in order to compare the calculated antiproton spectrum with experimental results, one also has to take into account the effect of solar modulation. In the force-field approximation \([52, 53]\) the effect of solar modulation can be included by applying the following relation between the antiproton flux at the top of the Earth’s atmosphere and the interstellar antiproton flux \([54]\):

$$\Phi_{\bar{p}}^{TOA}(T_{TOA}) = \left(\frac{2m_{p}T_{TOA} + T_{TOA}^{2}}{2m_{p}T_{IS} + T_{IS}^{2}}\right)^{1} \Phi_{\bar{p}}^{IS}(T_{IS}),$$

(3.21)

where $T_{IS} = T_{TOA} + \phi_{F}$, with $T_{IS}$ and $T_{TOA}$ being the antiproton kinetic energies at the heliospheric boundary and at the top of the Earth’s atmosphere, respectively, and $\phi_{F}$ being the solar modulation parameter, which varies between 500 MV and 1.3 GV over the eleven-year solar cycle. Since experiments are usually undertaken near solar minimum activity, we will choose $\phi_{F} = 500$ MV for our numerical analysis in order to compare our predicted flux with the collected data. For the antiprotons, we will not examine the background from spallation, but simply require that the fluxes from dark matter decay lie appropriately below the measurements so as to be compatible with predominantly secondary antiproton production.

4 Results

Below, we will present our results for the cosmic-ray signatures of decaying neutralinos and decaying hidden gauginos.\(^4\) In both cases, we will start with an analysis of the predictions that follow when assuming that the visible sector is described by an exemplary point in the coannihilation region of the mSUGRA parameter space. This ensures a consistent cosmology in the visible sector and that all free parameters of the MSSM are fixed. After that, we will go beyond this mSUGRA scenario and discuss how the cosmic-ray signatures can change in more generic cases. This will include a discussion about cascade decays in light of the apparent double-peak structure of the ATIC data.

4.1 Decaying neutralinos

The potentially relevant decay modes for the case $M_{X} < M_{\chi_{0}^{0}}$, where the lightest neutralino can decay into the hidden gaugino, are summarized in table 1. Beside three body decays, which produce fermion/anti-fermion pairs, we also have to take into account the decay into Higgs and $Z^{0}$ bosons. Throughout the analysis we will assume that the lightest neutralino $\chi_{1}^{0}$ makes up the dominant part of the dark matter, $\rho_{\chi_{1}^{0}} \simeq \rho_{DM}$.

**mSUGRA point.** As stated above, our exemplary mSUGRA model lies in the coannihilation region. The defining parameters are $m_{0} = 150$ GeV, $m_{1/2} = 720$ GeV, $A_{0} = 0$, $\tan \beta = 10$ and $\text{sign} \mu = +1$. In this model the lightest neutralino has a mass of 301 GeV and the correct relic density to be dark matter, $\Omega h^{2} \simeq 0.104$.\(^5\) As typical for models in the coannihilation region, the three right-handed sleptons have masses around 304 – 307 GeV,

\(^4\)For a short discussion of our model in light of the new Fermi electron data \([55]\) see the appendix.

\(^5\)The mass spectrum and relic abundance were calculated with the aid of DarkSUSY 5.0.4 \([56]\).
Branching Ratios for $\chi_1^0 \rightarrow \tau^+\tau^-$, for different hidden gaugino masses $M_X$. In the visible sector, masses and mixing parameters are fixed by a mSUGRA scenario in the coannihilation region as described in the text. The lightest neutralino has a mass of 301 GeV. Branching ratios of three-body decays into neutrinos, $\chi_1^0 \rightarrow \nu\bar{\nu}X$, and quarks, $\chi_1^0 \rightarrow q\bar{q}X$, are smaller than 0.3% and 0.02%, respectively. The two-body decay into photons, $\chi_1^0 \rightarrow \gamma X$, is one-loop suppressed and neglected. We also indicate the lifetime of the neutralino which gives the best fit to the data.

Table 4. Branching ratios for the decay of a neutralino $\chi_1^0$ into a lighter hidden gaugino $X$, for different hidden gaugino masses $M_X$. In the visible sector, masses and mixing parameters are fixed by a mSUGRA scenario in the coannihilation region as described in the text. The lightest neutralino has a mass of 301 GeV. Branching ratios of three-body decays into neutrinos, $\chi_1^0 \rightarrow \nu\bar{\nu}X$, and quarks, $\chi_1^0 \rightarrow q\bar{q}X$, are smaller than 0.3% and 0.02%, respectively. The two-body decay into photons, $\chi_1^0 \rightarrow \gamma X$, is one-loop suppressed and neglected. We also indicate the lifetime of the neutralino which gives the best fit to the data.

which is similar to the mass of the lightest neutralino. The left-handed sleptons have masses around 500 GeV. Furthermore, this particular mSUGRA point, which features e.g. a spin-independent cross section per proton of $2.6 \times 10^{-46}$ cm$^2$, can be probed with the next-to-next generation direct DM detection experiments like XENON1T and LUX/ZEP.

The dominant branching ratios of the neutralino decay are summarized in table 4, for different masses of the hidden gaugino. Most interestingly, the fraction of decays into charged leptonic final states is never below $\sim 65\%$. Beside the small masses of the right-handed sleptons, the underlying reason is the large $\mu$-term, $\mu = 865$ GeV, which suppresses the mixing between the bino-like lightest neutralino $\chi_1^0$, the hidden gaugino and the higgsinos like $\sim O(M_Z/\mu)$. Furthermore, for large enough masses of the hidden gaugino, the decay into $h^0X$ becomes kinematically forbidden.

Note that although we present a concrete mSUGRA model for definiteness, the branching ratios shown here are typical for mSUGRA models in the coannihilation region, provided that the $\mu$-term is large enough. If the latter is the case, three-body decays into charged leptons dominate over two-body decays into Higgs and gauge bosons.

To obtain the energy distribution of gamma rays, positrons and antiprotons that are produced in the neutralino decay, we used the event generator PYTHIA 6.4 [59]. From these spectra, the contribution to cosmic-ray fluxes as measurable at Earth can be derived as described in the previous section. Note that the lifetime of the neutralino is always fixed by requiring a qualitatively good agreement with the positron fraction as measured by PAMELA.

Our results are shown in figure 1. We find that in principle the model can account for the observed excess in the positron fraction around 10-100 if the hidden gaugino is light with a mass $M_X \lesssim 50$ GeV, although the predicted peak seems to rise too slowly to fully match the PAMELA data. This slow rise is due to the two-body decay into Higgs bosons, whose subsequent fragmentation produces rather soft positrons. From the lower plots of figure 1 it is apparent that the model is compatible with the EGRET measurements of the extragalactic gamma-ray background. However, the contribution to the antiproton flux can

[6] The calculations were done with FeynArts 3.4 and FormCalc 5.4 [57, 58].

[7] Gamma rays with energies below $\sim 10$ GeV stem from the fragmentation of the Higgs boson whereas gamma rays at higher energies mainly come from $\tau$ decay.
As 10 and 110 we aimed to fit the PAMELA data. Since we restricted ourself to use the background fluxes of course, the peak in the order of magnitude in both directions is common to all simultaneous fits to ATIC and PAMELA when using the above backgrounds. The agreement with ATIC, while at the same time flattening the positron fraction somewhat. Note that this A TIC data around 300-800 GeV cannot be reproduced in this setup.

We used the MED propagation model. In the lower left plot, the grey lines indicate the flux without handed sleptons have a mass around 1 µ. Value of the underlying MSSM model, the above plots can mainly change in two ways. Firstly, a larger

Idealized three-body decay of a heavy neutralino. For different parameters of the underlying MSSM model, the above plots can mainly change in two ways. Firstly, a larger value of the µ-parameter would reduce the branching ratio into Higgs and Z0 bosons. As a result, the rise in the positron fraction would be steeper, and the contribution to the

---

8 Note that the uncertainty in the antiproton flux at Earth from dark matter decay can be as large as one order of magnitude in both directions [10], due to our ignorance of the precise propagation parameters.

9 In figure 1 we aimed to fit the PAMELA data. Since we restricted ourself to use the background fluxes from ref. [7], as described above, this results in an electron+positron flux that lies above the ATIC data points at energies below 100 GeV. A lower normalization of the background flux of primary electrons would increase the agreement with ATIC, while at the same time flattening the positron fraction somewhat. Note that this behavior is common to all simultaneous fits to ATIC and PAMELA when using the above backgrounds. The same reasoning holds for figures 2, 3 and 5.

10 A concrete lower bound on the µ-parameter is extremely model-dependent. However, in the concrete scenario with a bino-like lightest neutralino where we take tan β = 10, αs = −0.1 and assume that the right-handed sleptons have a mass around 1.02 · Mν, the lower bound µ > O(2Mν) turns out to be sufficient to suppress the branching ratio into Higgs bosons below 20%.
we show our results for the cosmic-ray fluxes in the idealized case where a bino-like neutralino decays only via virtual right-handed sleptons. This resembles scenarios where the neutralino decays democratically into all three flavors. Positron fraction, total electron+positron flux and extragalactic gamma-ray flux for an idealized, three-body decaying bino-like neutralino. We neglect effects from $h^0$ and $Z^0$ bosons and assume pure democratic three-body decay into charged lepton pairs. The masses of the neutralino and the hidden gaugino are 500 GeV and 150 GeV (thick solid lines) or 1850 GeV and 300 GeV (thick dotted lines), respectively. The thin lines show the predictions when the decay into the tau-channel is neglected. The mass of the right-handed sleptons is assumed to be by a factor 1.1 larger than the neutralino mass.

antiproton flux smaller. Secondly, a higher mass of the decaying neutralino would shift the peak to higher energies, as suggested by the ATIC data.

In figure 2 we show our results for the cosmic-ray fluxes in the idealized case where a bino-like neutralino decays only via virtual right-handed sleptons. This resembles scenarios with a large $\mu$-term and large masses for the left-handed sleptons. The masses of the hidden gaugino and the neutralino $\chi^0_1$ are 150 GeV and 500 GeV (solid lines) or 300 GeV and 1850 GeV (dotted lines), respectively. Note that the thick lines correspond to the standard case where the neutralino decays democratically into all three flavors.

As expected, the rise in the positron fraction is now steeper and can easily accommodate the PAMELA data. Furthermore, a very heavy neutralino around 1.8 TeV allows to also account for the ATIC excess. In any case we find a clear excess in the extragalactic gamma-ray flux at energies above 10 GeV.

The gamma rays come mainly from $\tau$ decays and bremsstrahlung, but the latter is a subdominant effect as long as the three-body decay into charged leptons is democratic. However, the decay into taus can be suppressed in cases where the stau mixing angle is large, since the correspondingly larger left-handed component of the lighter stau weakens the coupling to the bino-like neutralino and the hidden gaugino. For example, if the lighter stau is equally left- and right-handed, the three-body decay into taus would be suppressed.
by a factor of $\sim 0.5$. To obtain a lower bound on the predicted gamma-ray signal, we also show the case where the neutralino decays into the first two generations only (see thin lines in figure 2). The gamma-ray flux is much smaller in this case and comes mainly from bremsstrahlung of the electrons produced in the three-body decay $\chi_1^0 \rightarrow e^- e^+ X$. Note that in any case we obtain a tight correlation between the contributions to the positron flux and the extragalactic gamma-ray flux, where the latter comes mainly from $\tau$ decays in most cases.

Heavy bino-like neutralinos with masses above a few hundred GeV are problematic for cosmology since they are typically overproduced, even when coannihilation with sleptons is taken into account. At the same time, wino- and higgsino-like lightest neutralinos do not exhibit the desired leptophilic decay. However, these problems are absent if one considers scenarios where the hidden gaugino is heavier than the lightest neutralino, $M_X > M_{\chi_1^0}$. Firstly, due to the mixing with the bino, the interactions of the hidden gaugino are automatically "bino-like". Secondly, for the small mixings that we consider bounds from overproduction arguments are irrelevant $[30]$. Note that the results from this paragraph can also hold in that case, provided one exchanges the roles of the hidden gaugino and the lightest neutralino. However, this requires that all sparticles, apart from the lightest neutralino, are heavier than the hidden gaugino. Generically this will not be the case and the hidden gaugino will cascade-decay through the different sparticles down into the lightest neutralino. We will consider this in detail in the next subsection.

4.2 Decaying hidden gauginos

A hidden gaugino that is heavier than the lightest neutralino, $M_X > M_{\chi_1^0}$, turns out to be more appealing from the phenomenological point of view. In this case, the mass of the lightest neutralino can be small and of the order of a few 100 GeV, and the hidden gaugino automatically possesses the “bino-like” interactions which are desirable for the leptophilic decay. We will again assume that the lightest neutralino makes up most of the dark matter, whereas the hidden gaugino contributes only a subdominant part $\rho_X \ll \rho_{\chi_1^0}$ to the overall matter density of the Universe. Note that in this case the lifetime of the hidden gaugino can be as small as $\tau_X \sim 10^{17}$ s, the current age of the Universe, provided that its relic abundance is small enough. For definiteness, we will take $\rho_X = 10^{-3} \rho_{\chi_1^0}$ throughout this section.

We will firstly discuss the contributions from the decaying hidden gaugino to the cosmic-ray flux as predicted for our reference mSUGRA scenario. Secondly we will consider the multi-peak structure of a cascade-decaying hidden gaugino in light of the ATIC data.

mSUGRA point. The considerations in this paragraph are again based on the mSUGRA scenario described above. Depending on the mass of the hidden gaugino, its decay can produce fermions, neutralinos, charginos, Higgs and gauge bosons as depicted in table 1. The corresponding branching ratios are summarized in table 5, where we do not show the subsequent decays of the neutralinos $\chi_i^{0,3,4}$ and charginos $\chi_i^{\pm}$ for simplicity.$^{12}$

As apparent from table 5, the decay into charged lepton/slepton pairs is dominant in the whole mass range $M_X \sim 600 - 1600$ GeV that we consider. The decay into quarks is suppressed by the large squark masses, $m_{\tilde{q}} \gtrsim 1.1$ TeV, whereas decay into $h^0$, $Z^0$ and $W^\pm$ bosons is mainly suppressed by the small mixing between higgsinos and the hidden gaugino. $^{11}$

$^{11}$Winos only couple to left-handed sleptons, which are typically heavier than the right-handed ones, whereas higgsinos can easily decay into the Higgs boson.

$^{12}$These subsequent decays are taken into account in our calculations. We singled out the dominant decay modes in our reference mSUGRA model and used them in the PYTHIA code: $X \rightarrow h^0 \chi_4^0$, $X \rightarrow Z^0 \chi_4^0$, $X \rightarrow W^\mp \chi_2^\pm$, $\chi_3^0 \rightarrow \chi_4^0 Z^0$, $\chi_4^0 \rightarrow \chi_1^0 h^0$ and $\chi_2^\pm \rightarrow \chi_1^\mp Z^0$ (28%), $\chi_2^+ h^0 (27%)$, $\chi_2^0 W^\pm$ (36%). The decay of $\chi_2^0$ and $\chi_1^+$ only produces leptons and is neglected.
gaugino. However, this mixing can become enhanced when the masses of the higgsinos become comparable to the mass of the hidden gaugino, which happens around $M_X \sim 870$ GeV.

Our results for the cosmic-ray fluxes are shown in figure 3 for hidden gaugino masses

\begin{table}

\caption{Positron fraction, extragalactic gamma-ray flux, antiproton flux and total electron + positron flux from the decay of a hidden gaugino as predicted by our mSUGRA scenario. The branching ratios are shown in table 5. The mass of the hidden gaugino varies between 600 GeV (solid), 800 GeV (dotted), 1000 GeV (dashed) and 1200 GeV (dot-dashed).}
\end{figure}
Figure 4. Energy spectrum of positrons from an idealized cascade-decaying hidden gaugino. Only two-body decay into right-handed slepton/lepton pairs is taken into account. The slepton subsequently decays into the lightest neutralino. The spectrum exhibits two pronounced peaks, which we denote by $E_h$ and $E_l$. We show plots for a lightest neutralino with mass 150 GeV (solid) and with 1 TeV (dashed). The position of the peaks is fixed to $E_h = 700$ GeV and $E_l = 200$ GeV, as suggested by the ATIC data. The masses of the right-handed sleptons follow then from eq. (4.1). We also indicate the part of the positrons that comes solely from the tau/stau decay channel (blue area).

between 600 GeV and 1200 GeV, where we adjusted the lifetime of the hidden gaugino to fit the PAMELA data. For all masses of the hidden gaugino that we consider, the predictions for the positron fraction are in qualitatively good agreement with the PAMELA data. At the same time, the contribution to the antiproton flux lies well below the measurements and hence is safe in all cases. Furthermore, we obtain contributions to the extragalactic gamma-ray flux, which are mainly due to $\tau$ decays. They are compatible with the EGRET measurements but could show up in future experiments as an excess above background. The total electron+positron flux is also compatible with the different measurements and we predict a sharp step at high energies.

**Multi-peak structures from cascade decays.** As already evident in figure 3, the energy distribution of particles produced in cascade decays in general features several peaks. Their exact position carries information about the masses of the different intermediate particles. It is intriguing to speculate that the apparent double-peak structure of the ATIC data originates from cascade-decaying particles [12].

In the case of the decaying hidden gaugino, the energy spectrum of positrons in general possesses two pronounced peaks. These peaks stem from decays with intermediate selectrons. To simplify the discussion, we will neglect decay modes that produce $h^0$, $Z^0$, and $W^\pm$ bosons or left-handed sleptons, and we will assume democratic decay into all three flavors. If we furthermore assume approximate mass degeneracy for the three right-handed sleptons, we are left with only three free parameters: the mass of the hidden gaugino $M_X$, the mass of the lightest neutralino $M_{\chi^0_1}$, and the mass scale of the right-handed sleptons $M_{l_R}$.

In figure 4 we show the corresponding energy spectrum of positrons for two different

---

Note, however, that the recently released electron data from the Fermi satellite [55] does not confirm the double peak structure seen by ATIC. For a discussion about the implications of the new data for our model see the appendix. Other explanations for double-peak structures can be found in ref. [60].
sets of particle masses. The two pronounced peaks are denoted by $E_h$ and $E_l$. Fixing the neutralino mass and the position of the peaks determines the slepton and hidden gaugino masses according to

$$M_{l_R}^2 = M_{\chi_0^+}^2 + 2E_l^2 \left( \frac{E_h}{E_l} - 1 \right)^2 + \left( \frac{M_{\chi_0^+}}{E_l} - E_h/E_l + 1 \right) = E_h + \sqrt{E_h^2 + M_{l_R}^2}. \quad (4.1)$$

As a simple attempt to fit the ATIC data with an idealized cascade-decaying hidden gaugino, we take the values $E_h = 700$ GeV and $E_l = 200$ GeV. After this, a neutralino mass of $M_{\chi_0^+} = 150$ GeV (1000 GeV) implies a slepton mass of $M_{l_R} = 177$ GeV (1117 GeV) and a hidden gaugino mass of $M_X = 1422$ GeV (2018 GeV).

The resulting cosmic-ray fluxes for the two neutralino masses are shown in figure 5 (upper plots, thick lines), where we used the MED propagation model. Interestingly, the predicted fluxes are practically the same for the two cases, although the bump structure is slightly enhanced in case of the heavier neutralino. The lower plots are based on the M2 propagation model as an exemplary model with a thin diffusion zone, $L = 1$ kpc (as opposed to $L = 4$ kpc in case of the MED model). Since in these scenarios electrons and positrons are

![Figure 5](image-url)
more likely to escape the diffusion zone before having lost much of their energy, the observable spectrum becomes steeper. This effect can improve the agreement with the sharp features of the ATIC data. However, note that propagation models with thin diffusion zones have problems with the correct prediction of the flux of unstable isotopes like $^{10}\text{Be}$ or $^{14}\text{C}$ [61].

Up to now we have assumed a vanishing stau mixing angle and democratic decay into all three flavors. However, if the stau mixing angle is large the decay mode into tau/stau pairs would be suppressed, as discussed above. In figure 4 we indicated the part of the positrons that comes from the stau/tau channel in the case of democratic decay (blue region). A suppression of this channel can lead to a relative enhancement of the two-peak structure of the cascade decay. This effect is shown by the thin lines in figure 5, where we only took into account the decay modes into muon/smuon and electron/selectron pairs. As expected, the peaks at high energy become more pronounced, and the spectrum becomes harder at low energies, although the effect is not dramatic.

5 Conclusions

In this work we have shown that a simple extension of the MSSM by an additional hidden Abelian gauge group $U(1)\times Y$, which kinetically mixes with the hypercharge $U(1)\gamma$, can account for the observed PAMELA excess if the kinetic mixing parameter is in the range of $\chi \sim 10^{-(20\ldots24)}$. We also briefly discussed possible origins of such a tiny mixing in scenarios with warped extra dimensions. Depending on the masses, either the visible-sector neutralino or the hidden gaugino becomes unstable and subject to decay. We have demonstrated that this decay is dominated by leptonic modes in certain parameter regions of the MSSM where the sleptons are light (see table 4 and table 5). We found that a decaying hidden gaugino with a mass around 600 – 1200 GeV can naturally explain the observed excess in the positron fraction without overproducing antiprotons (see figure 3). Furthermore, we showed that it is difficult to accommodate a sharp double-peak structure as observed by ATIC within our setup and with standard propagation models. Our considerations suggest a preference for supersymmetric models with relatively light sleptons, as e.g. realized in mSUGRA models which lie in the coannihilation region. In any case, we predict a contribution to the extragalactic gamma-ray flux, which mainly stems from tau decays, and which should be observable by future experiments like the Fermi Gamma-ray Space Telescope.

Acknowledgments

We would like to thank A. Strong for providing a convenient compilation of cosmic-ray data. Furthermore, CW gratefully acknowledges G. Sigl for helpful discussions and the Technische Universität München for kind hospitality. AI and DT would like to thank the Yukawa Institute for Theoretical Physics and the CERN Theory Division for hospitality during the last stages of this work. The work of AI and DT was partially supported by the DFG cluster of excellence “Origin and Structure of the Universe.”

During the last stages of our work a preprint appeared that also examines hidden gauginos in the context of the PAMELA/ATIC anomalies, coming to similar conclusions [63].

\[14\] Furthermore, the change of the propagation model in principle also changes the predictions for the background of secondary positrons, which were calculated for the above M1, M2 and MED model in ref. [62]. However, in figure 5 we used the background from ref. [2] since the backgrounds obtained in ref. [62] are meant to be extreme cases.
Figure 6. Positron fraction and total electron+positron flux for an idealized, three-body decaying bino-like neutralino with mass 2500 GeV, decaying into a light hidden gaugino. We also show the new Fermi LAT [55] and H.E.S.S. [64] data points.

A Implications of recent Fermi LAT results

The recently released measurement of the cosmic-ray electron+positron spectrum from the Fermi LAT [55] does not confirm the distinct feature seen by the ATIC experiment. Instead, Fermi LAT observes a smooth, hard spectrum, which follows a power law $\sim E^{-3.0}$ up to energies of 1 TeV. As indicated by the H.E.S.S. observations [64], this power law further steepens at energies above 1 TeV.

In figure 6 we show the results for a three-body decaying bino-like neutralino, as discussed in section 4.1. The mass of the neutralino is 2500 GeV, whereas the hidden gaugino has a small mass $\sim O(100 \text{ GeV})$. In the plots we assume that the decay is only mediated by right-handed sleptons with a mass close to the neutralino mass. All other supersymmetric particles must be heavy enough to make their effects on the branching ratios negligible. However, although this scenario is phenomenologically appealing, it requires some non-standard cosmology in order to avoid the thermal overproduction of the heavy bino-like neutralino. A second way to explain the data measured by Fermi would be a cascade-decaying hidden gaugino, see section 4.2. The sharp step in the electron+positron spectrum, as shown in figure 3, disappears if the first generation sleptons are heavy enough to suppress the production of electrons or positrons in two-body decays. This, however, requires non-universal slepton masses.

Note that in both of the above cases, the production and decay of taus will lead to a visible bump in the extragalactic gamma-ray flux, which should be measurable by the Fermi LAT.
