Intra-arrest thrombolysis in pulmonary thromboembolism with a successful clinical and neurological outcome: a case report

Abstract

Pulmonary thromboembolism is a highly fatal entity, and usually presents atypically. Between 80 and 90% of cases of cardiorespiratory arrest secondary to pulmonary embolism occur between 1 and 3 hours after the onset of symptoms, requiring a high degree of clinical suspicion as patient management and prognosis will depend on this. We present the case of a 72-year-old man, admitted after gastrointestinal symptoms and syncope, and who presented cardiorespiratory arrest while in the emergency room. Prior to the circulatory arrest, signs of right ventricular dysfunction and intracavitary thrombi were documented, so systemic thrombolysis was administered overall during resuscitation maneuvers. Subsequently the patient evolved successfully with no cardiac or neurological dysfunction.

Keywords: pulmonary thromboembolism, cardiorespiratory arrest, thrombolytic therapy, echocardiography

Case report

A 72-year-old male, with no pathological or family history, presents with dizziness, abdominal pain and non-dysenteric diarrheic depositions together with a syncopal episode lasting a few minutes, presenting a full recovery without neurological deficit. 15 minutes later he enters emergency services alert, with no other symptoms, hydrated, with increased peristalsis. Parenteral hydration and initial paraclinical exams (ionogram, hemogram and electrocardiogram) are considered during his time at the emergency services, with no alterations evident. The electrocardiogram returned a sinus rhythm, no tachycardia, no signs of acute ischemia, no blockages.

As the patient improved with hydration, the decision is made to release him. After this, the patient’s upper extremities begin to move rigidly, and his eyes deviate to the left side. The patient then states he feels dizzy and weak overall, he looks pale and then presents persistent hypotension, extreme bradycardia, distal coldness and desaturation. Ultrasound tracing of the subxiphoid window was performed with ultrasound imaging within the ventricles. Thrombolysis is begun using a recombinant tissue plasminogen activator 100mg IV over 2 hours. After this is started, the patient goes into pulseless electrical activity cardiac arrest. Cerebral pulmonary reanimation maneuvers are performed. Bicarbonate (7 direct ampoules) is used, and the dose of the recombinant tissue plasminogen activator thrombolytic agent changed to 50mg via bolus. After 35 minutes of reanimation, the patient regains spontaneous circulation with a sinus rhythm, no tachycardia, no signs of acute ischemia, no blockages.

Subsequently, he is transferred for an angiotomography of the pulmonary vessels where acute thrombi are identified in the main pulmonary arteries on both sides and in the segmental branches in the upper and lower lobes.

Figure 1A Alterations in the size of the right ventricle, decreasing compared to the left ventricle.

Figure 1B Deviated septum.
The patient is transferred to the Intensive Care Unit where he continues under observation for XX days. An official transthoracic echocardiogram is then performed, finding dilation of the right ventricle, a high probability of pulmonary hypertension (49mmHg), no systolic or diastolic dysfunction of the left ventricle, with an estimated ejection fraction of 55%. Tolerates extubation and removal of hemodynamic support at XX days.

Released from the hospital with oral anticoagulants after XX days with no neurological sequelae and no need for supplementary oxygen.

Discussion

Pulmonary embolism (PE) is a highly fatal condition and tends to present atypically or non-specifically, as was the case with the patient presented above. Because it compromises the pulmonary and cardiovascular systems it can have different manifestations, meaning that clinicians must employ a high degree of diagnostic suspicion when attending patient, with early recognition of red flags during care or conditions that could put the patient’s life at risk in the following minutes.

The annual estimated incidence in the United States is between 1 and 2 cases per 1000 inhabitants, with 30% mortality rates when presenting as thromboembolism with signs of shock. In the case of cardiorespiratory arrest the associated mortality rate increases by up to 95%. There are reports in postmortem studies of unrecognized pulmonary embolism in 84% of cases, or, on the contrary, it is overdiagnosed in 5-25% of cases due to subsegmental pulmonary location, recent high slice CT scanners, radiology experience for the interpretation of other artefacts, among other factors.

Between 80 and 90% of cardiorespiratory arrest cases secondary to pulmonary embolism occur 1 to 2 hours after symptoms begin. This is because thrombi are generated that can embolize pulmonary circulation giving rise to initial respiratory symptoms. This is because thrombi are generated that can embolize pulmonary circulation giving rise to initial respiratory symptoms. The IOPER registry included 2110 patients with confirmed PE and followed them for 3 months, describing that patients had an average age of 62 years and the main symptoms described were: dyspnea (82%), chest pain (49%), cough (20%), syncope (14%), hemoptysis (7%), among others. The EMPEROR registry implemented multicentrically in hospitals, or 30-day survival late when compared to a placebo.

In the most recently updated guidelines recommend its use in emergency situations (Class IIa, LOE B) such as cardiorespiratory arrest due to improved reanimation outcomes in some of them.

Most studies of cardiopulmonary resuscitation in the context of pulmonary embolism are retrospective, have concluded that it is superior to standard treatment, but have many limitations (insufficient number of patients, short-term outcomes, selection bias, among others).

During emergency care for this patient no CT confirmation could be performed due to rapid clinical instability, the need to secure his airways, and the early start of reanimation maneuvers. For this reason, a bedside ultrasound is performed on the patient, seeking signs of pulmonary embolism, including free intracavitary thrombi or thrombi in the pulmonary artery (as presented in this patient), or indirect signs like dilation of the Right Ventricle vs the Left Ventricle (≥:1:1 RV/LV), systolic disfunction of the right ventricle, sepsis or hemodynamic support at XX days.

Released from the hospital with oral anticoagulants after XX days with no neurological sequelae and no need for supplementary oxygen.

AHA guidelines there is no evidence available to support or refute the effectiveness of empirical thrombolysis in suspected but unconfirmed pulmonary embolism.

Conclusions
Pulmonary embolism is a frequent entity that can be extremely deadly in the event it causes clinical instability or leads to cardiorespiratory arrest in patients. For this reason, a high degree of clinical suspicion should be employed to ensure timely management. In the presented patient it was shown that the return of spontaneous circulation was benefited by the application of intra-arrest thrombolysis, with a good clinical (hemodynamic, cardiac, respiratory) and neurological outcome at the time of release.
