DMSP biosynthesis by an animal and its role in coral thermal stress response

Jean-Baptiste Raina1,2,3, Dianne M. Tapiolas2, Sylvain Forêt3,4, Adrian Lutz2,3,5, David Abrego2‡, Janja Ceh6, François O. Seneca1,2‡, Peta L. Clode7,8, David G. Bourne5, Bette L. Willis1,3 & Cherie A. Motti2

Globally, reef-building corals are the most prolific producers of dimethylsulphoniopropionate (DMSP)1,2, a central molecule in the marine sulphur cycle and precursor of the climate-active gas dimethylsulphide3,4. At present, DMSP production by corals is attributed entirely to their algal endosymbiont, *Symbiodinium*. Combining chemical, genomic and molecular approaches, we show that coral juveniles produce DMSP in the absence of algal symbionts. DMSP levels increased up to 54% over time in newly settled coral juveniles lacking algal endosymbionts, and further increases, up to 76%, were recorded when juveniles were subjected to thermal stress. We uncovered coral orthologues of two algal genes recently identified in DMSP biosynthesis, strongly indicating that corals possess the enzymatic machinery necessary for DMSP production. Our results overturn the paradigm that photosynthetic organisms are the sole biological source of DMSP, and highlight the double jeopardy represented by worldwide declining coral cover, as the potential to alleviate thermal stress through coral-produced DMSP declines correspondingly.

It is widely accepted that the production of dimethylsulphoniopropionate (DMSP), a central molecule in the marine sulphur cycle, restricted to marine algae and a few species of intertidal plants5. Marine bacteria subsequently use DMSP as a source of sulphur and carbon and can metabolize this compound into the volatile gas dimethylsulphide (DMS), by which the largest natural flux of sulphur enters the atmosphere where it exerts considerable influence on atmospheric chemistry6. Despite recent controversy regarding the impact of DMS emissions on global climate7, DMS is probably involved in local climate regulation through its oxidation into aerosol particles that induce the formation of clouds and increase their reflectivity, thereby reducing light levels and water temperatures in the marine environment8,9.

Concentrations of DMSP and DMS found in reef-building corals are among the highest recorded in the environment10, but it has been assumed that DMSP production derives solely from the coral’s endosymbiotic microalgae *Symbiodinium*. Evidence that the total amounts of DMSP recorded in corals are consistently higher than levels present in *Symbiodinium* cells alone11,12 raises the possibility of a cryptic source of DMSP in reef-building corals. A clear understanding of the sources of DMSP on reefs and the possible effects that global warming may have on DMSP production is paramount, given the influence that coral-reef-derived sulphur emissions may have on local climates13. Corals in the genus *Acropora* are the most abundant reef-building organisms in the Indo-Pacific region14 and, as broadcast spawners, they acquire *Symbiodinium* from their surrounding environment after larval development. The *Symbiodinium*-free larvae of this genus provide a unique opportunity to investigate *Symbiodinium*-independent production of DMSP in corals. Results presented here demonstrate that coral hosts (kingdom: Animalia) are capable of biosynthesizing DMSP in high concentrations in the absence of symbiotic microalgae, refuting the current paradigm that photosynthetic organism are the only DMSP sources in the environment.

DMSP levels were quantified in juveniles lacking photosynthetic symbionts for two common coral species, *Acropora millepora* and *A. tenuis*, using nuclear magnetic resonance (NMR) spectroscopy15. Juveniles were raised in the dark in 0.2-µm-filtered seawater to ensure they remained algae-free, and the absence of any photosynthetic organisms in these juveniles was confirmed using five different DNA markers, ranging from *Symbiodinium*-specific to universal 235 RNA plastids primers, targeting all eukaryotic algae and cyanobacteria. A lack of any detectable amplification was observed for all markers (Extended Data Tables 1 and 3). Despite the complete absence of any photosynthetic microalgae, high concentrations of DMSP, two orders of magnitude greater than concentrations reported for benthic algae from the Great Barrier Reef16, were recorded in all coral juvenile samples (Fig. 1). Repeated sampling over a 6-day period after larval settlement revealed that the initially high DMSP concentrations in juveniles increased significantly over time; specifically, DMSP increased by 44% (that is, 1.1 nmol mm⁻²) in *A. millepora* and by 54% (that is, 1.7 nmol mm⁻²) in *A. tenuis* (ANOVA, n = 6, P < 0.005; Fig. 1 and Extended Data Table 2). These results demonstrate unambiguously that the DMSP levels measured were not inherited from parent colonies but instead were produced by coral juveniles growing in the absence of photosynthetic symbionts.

Increases in DMSP concentrations over time were even more pronounced when coral juveniles experienced thermal stress (32°C), with *A. tenuis* and *A. millepora* exhibiting 65% and 76% increases over the 6-day experimental period, respectively (ANOVA, n = 6, P < 0.005; Fig. 1 and Extended Data Table 2). Conversely, concentrations of the DMSP breakdown product acrylate decreased in both species, with thermally stressed juveniles containing 33% (*A. millepora*) and 61% (*A. tenuis*) less acrylate after 6 days than juveniles at ambient temperature (Fig. 1c, d). Similar declines in acrylate in marine algae subjected to stressful conditions17,18 have been related to its antioxidant properties; acrylate and DMS are both extremely efficient scavengers of hydroxyl radicals and other reactive oxygen species (ROS)19. During thermal stress, the production of ROS by coral mitochondria (and *Symbiodinium*, when present) increases, damaging coral cells20. The observed decrease in acrylate concentrations in thermally stressed coral juveniles probably reflects its involvement in ROS detoxification, implicating DMSP and its breakdown products as functionally important in coral stress responses.

Further experimental studies involving adult corals, the building blocks of coral reefs and the most ecologically relevant life history stage in terms of DMSP production, confirm the importance of this
that 100% of the remaining production. Furthermore, transmission electron microscopy showed that Symbiodinium were unlikely to contribute significantly to DMSP cell densities (Extended Data Fig. 1a and Fig. 2a–c), thus photosynthetic algae are not the exception, rather than the rule, in terms of DMSP production by eukaryotes (Extended Data Fig. 3), indicating that corals are likely to be restricted to juvenile life stages, but also occurs at high levels in adult reef-building corals subjected to thermal stress. In addition to its antioxidant role, DMSP is involved in several key cellular and ecological processes in reef-building corals, notably as an osmoprotectant during salinity fluctuations, but also as a signal molecule attracting specific bacteria which form microbial communities that are integrally associated with corals and underpin their health14. The multiple functions of this molecule might explain the ecological advantage of producing it directly.

To further support our conclusion that DMSP is produced by the coral host, we examined potential molecular mechanisms underlying their DMSP biosynthetic capabilities. In some marine algae, DMSP is produced from methionine via a pathway that involves the successive action of four different enzymes19, but until recently, very little was known about genes involved in its biosynthesis. A recent study identified candidate genes for each of the four steps of the biosynthesis pathway in the diatom Fragilariaopsis cylindrus20. We searched for potential orthologues of these genes in the comprehensive molecular resources available for two coral species, the A. millepora transcriptome21 and the Acropora digitiﬁera genome22, and found that two genes identified in diatoms have clear orthologues in corals. These genes encode a NADPH-reductase and an AdoMet-dependant methyltransferase, which mediate the second and third steps of the biosynthesis process, respectively (Fig. 3a). The orthologous relationship between the corals’ and diatom’s genes is supported by best reciprocal blast hits and their mapping to the same OrthoMCL clusters23 (Extended Data Table 4). We also identiﬁed two Symbiodinium orthologues (from a comprehensive transcriptome assembly24) belonging to the same OrthoMCL clusters as the reductase and methyltransferase identiﬁed in diatoms and corals (Extended Data Table 4). This indicates that the function of these enzymes in DMSP biosynthesis may be conserved between diatoms, alveolates, green plants and corals.

Despite the severe degradation and depletion of algal symbionts from coral tissues, thermally stressed corals contained 68% more DMSP (that is, 9 nmol mm$^{-2}$) and concordantly 36% less acrylate than control colonies (Fig. 2). These results are in close accordance with those we found for coral juveniles. Taken together, our results provide conclusive evidence that the observed increases in DMSP concentrations in thermally stressed corals cannot be attributed to the activity of Symbiodinium cells. This implies that DMSP production is not restricted to juvenile life stages, but also occurs at high levels in adult reef-building corals subjected to thermal stress. In addition to its antioxidant role, DMSP is involved in several key cellular and ecological processes in reef-building corals, notably as an osmoprotectant during salinity fluctuations, but also as a signal molecule attracting specific bacteria which form microbial communities that are integrally associated with corals and underpin their health14. The multiple functions of this molecule might explain the ecological advantage of producing it directly.

To further support our conclusion that DMSP is produced by the coral host, we examined potential molecular mechanisms underlying their DMSP biosynthetic capabilities. In some marine algae, DMSP is produced from methionine via a pathway that involves the successive action of four different enzymes19, but until recently, very little was known about genes involved in its biosynthesis. A recent study identified candidate genes for each of the four steps of the biosynthesis pathway in the diatom Fragilariaopsis cylindrus20. We searched for potential orthologues of these genes in the comprehensive molecular resources available for two coral species, the A. millepora transcriptome21 and the Acropora digitiﬁera genome22, and found that two genes identified in diatoms have clear orthologues in corals. These genes encode a NADPH-reductase and an AdoMet-dependant methyltransferase, which mediate the second and third steps of the biosynthesis process, respectively (Fig. 3a). The orthologous relationship between the corals’ and diatom’s genes is supported by best reciprocal blast hits and their mapping to the same OrthoMCL clusters23 (Extended Data Table 4). We also identiﬁed two Symbiodinium orthologues (from a comprehensive transcriptome assembly24) belonging to the same OrthoMCL clusters as the reductase and methyltransferase identiﬁed in diatoms and corals (Extended Data Table 4). This indicates that the function of these enzymes in DMSP biosynthesis may be conserved between diatoms, alveolates, green plants and corals.

Results derived from the A. millepora transcriptome21 enabled us to estimate the level of expression of these two genes throughout five life stages, from embryos to adults. We found the gene encoding the reductase, a reversible step in the DMSP biosynthesis process5, to be highly expressed throughout all life-history stages (Fig. 3b). The phylogenetic distribution of its OrthoMCL cluster revealed 45 orthologues spread throughout all kingdoms (Extended Data Fig. 3), in line with the widespread presence of this enzyme among plants that do not produce DMSP5. In contrast, the methyltransferase mediates a non-reversible step regulating intracellular DMSP levels25 and is believed to be speciﬁc to this pathway5. The gene encoding the methyltransferase was highly expressed in early coral life stages, but its expression decreased after settlement and remained relatively low in adult corals (Fig. 3c). This expression pattern correlates with the establishment of symbiosis with DMSP-producing Symbiodinium around the time of settlement. The OrthoMCL cluster corresponding to the methyltransferase has an unusually sparse phyletic pattern with only nine orthologues, including seven in photosynthetic organisms and two in other eukaryotes (Extended Data Fig. 3), indicating that corals are likely to be the exception, rather than the rule, in terms of DMSP production by marine invertebrates harbouring photosynthetic symbionts26.

We show that the unparalleled levels of DMSP present in reef-building corals are not attributable solely to their endosymbiotic algae; instead, a significant fraction is produced by the coral animal. DMSP concentrations measured in coral juveniles devoid of symbiotic algae represented approximately half of those present in symbiont-bearing adult corals, indicating that the coral animal contributes extensively to
the DMSP pool produced on coral reefs. Surveys over Australia identified the Great Barrier Reef as a significant hotspot for the emission of sulphur aerosol particles. The Great Barrier Reef is the largest biological structure on the planet and the release of these particles along its 2,600-km length could constitute a major source of cloud condensation nuclei. Coral-reef-derived sulphur aerosol emission might therefore have a central role in cloud formation in areas of the world with high coral densities, such as the Great Barrier Reef and the Coral Triangle. Considering declining trends in coral cover and predicted increases in coral mortality worldwide caused by anthropogenic stressors, the associated decline in sulphur aerosol production from coral reefs may further destabilize local climate regulation and accelerate degradation of this globally important and diverse ecosystem.

METHODS SUMMARY

Coral juvenile sampling. Coral larvae were raised for 12 days in 0.5-µm-filtered seawater (FSW), subsequently washed three times in 0.2-

METHODS

Adult corals
Thermal stress experiment. Acropora millepora colonies (n = 10) were collected from Pelorus Island, Great Barrier Reef, Australia (18°33’ S/146° 29’ E) and transferred to the Australian Institute of Marine Science. Coral colonies were fragmented to give a total of 24 fragments, each comprising approximately 25 branches (nubbins). Fragments were arranged in eight indoor tanks in a randomized block design, resulting in the allocation of 12 coral fragments to each of the control and thermal stress temperature treatments (27°C and 32°C, respectively). All tanks were continuously supplied with fresh 1-μm filtered seawater (FSW), which was maintained at 27°C ± 0.1°C via computer control using a flow-through system at a rate of 1.5 l min⁻¹. Ultraviolet- filtered lights were mounted above each tank and provided an average underwater light intensity of 350 μE m⁻² s⁻¹. A 12/12 h light/dark cycle (400 W metal halide lamps, BLV), typical of light intensities recorded at the collection site. The fragments were acclimatized for 2 weeks before starting the experiment. Seawater temperatures in four tanks were slowly and continuously ramped to 32°C ± 0.05°C over a 7-day period, via computer control, while the remaining four control tanks were maintained at 27°C for the entire duration of the experiment.

Coral nubbins were sampled four times during the experiment: before any temperature changes when both treatments were at 27°C (t = 0), after the coral nubbins had been reached in the thermal stress treatment (t = 0); after 5 days at 27°C, when the first physiological effects of temperature stress were visible (t = 5); and after 10 days at 32°C when all colonies in the 32°C treatment were completely bleached (t = 10). At each time point, one coral nubb (approximately 50 mm in length) was collected from each coral fragment (n = 24) and immediately transferred to a tube containing 2 ml of HPLC-grade methanol for quantitative nuclear magnetic resonance (qNMR) analysis. Another coral nubb was collected from each coral fragment (n = 24) to evaluate Symbiodinium densities. In addition, one coral nubb was collected at each time point from four different coral fragments, transferred directly into fixative (1.25% glutaraldehyde + 0.5% paraformaldehyde in 0.2-mM FSW) and stored at 4°C until processed for structural investigations by transmission electron microscopy (TEM).

Quantitative NMR analysis. The coral nubbins were extracted in methanol for 2 h with sonication followed by a second extraction with an additional 1 ml of HPLC-grade methanol for 10 min. The two extracts were pooled and dried using a vacuum-centrifuge then re-suspended in a mixture of deuterium oxide (D₂O, D 99.8%, 250 μl) and deuterated methanol (CD₂OD, D 99.8%, 750 μl) (Cambridge Isotope Laboratories). A 700 μl aliquot of the particulate-free extract was transferred into a 5-mm Norel 509-UP-7 NMR tube (Norel Inc.) and analysed immediately by 1H NMR.

1H NMR spectra were recorded on a Bruker Avance 600 MHz NMR spectrometer with T2X 5-mm probe and quantification performed using the ERETIC method30. This technique generates an internal electronic reference signal, calibrated using commercial stock solutions of 4 mM Acrylamide and DMSO. The concentrations of DMSO and acrylamide were determined by integration of their respective signals in a 0.10 p.p.m. window31.

Symbiodinium densities. Freshly collected coral nubbins were airbrushed (80 lb in 2) in individual plastic bags in 4 ml of 0.2-mM FSW. The slurries were homogenized to breakdown aggregates and centrifuged at 3,000 r.c.f. (relative centrifugal force). The supernatant was removed and the pellet re-suspended in 1 ml of 10% formalin. The coral nubbins were extracted in methanol for 2 h with sonication followed by a second extraction with an additional 1 ml of HPLC-grade methanol for 10 min. The two extracts were pooled and dried using a vacuum-centrifuge then re-suspended in a mixture of deuterium oxide (D₂O, D 99.8%, 250 μl) and deuterated methanol (CD₂OD, D 99.8%, 750 μl) (Cambridge Isotope Laboratories). A 700 μl aliquot of the particulate-free extract was transferred into a 5-mm Norel 509-UP-7 NMR tube (Norel Inc.) and analysed immediately by 1H NMR.

Transmission electron microscopy. Fixed coral nubbins were dehydrated in a formic acid/fixative mixture (1:3), with the solution changed every 12 h until complete dissolution of the skeleton. Three individual polyps per sample were post-fixed in osmium and subsequently dehydrated with increasing concentrations of ethanol followed by dry acetone. Dehydrated samples were infiltrated in increasing concentrations of Araldite resin before being cured for 24 h at 60°C. Longitudinal sections 90-nm thick were collected on copper grids and imaged at 120 keV in a JEOL 2100 TEM.

Pulse amplitude modulation (PAM) fluorometry measurements. Photosystem II (PSII) photochemical efficiency was measured with a Diving-PAM (Walz) on three random nubbins per coral fragment. Minimum and maximum fluorescence (F₀ and Fₚ), were recorded daily, 2 h before the start of the light cycle. PS II photochemical efficiency was expressed as maximum quantum yields (φPSII = (Fₚ − F₀)/(Fₚ)).

Data analyses. All data were square root transformed and no significant factor was detected for the DMSP, acrylamide and PAM fluorometry data (nest ANOVA, F = 0.05) (Statistica 7, Statsoft). The significance level was chosen based on results from a pilot study. Repeated measures ANOVA were carried out on the time series data (data met all assumptions of the test). Simple main effect tests34 were used to compare the results between the two temperature treatments, and between temperatures at each time point (Extended Data Table 3). This statistical technique was used to minimize the number of multiple comparisons (focusing only on comparisons of interest), decreasing the likelihood of type I error.

Coral juveniles
Sample collections. Colonies of A. millepora (n = 10) and A. tenuis (n = 3) were collected from Orpheus Island, Great Barrier Reef, Australia (18°34’ S/146° 30’ E) and transferred to the Australian Institute of Marine Science outdoor aquarium facility (4 days before the predicted spawning event in November 2011. One hour before spawning, the colonies were isolated in 70 l tanks with 1-μm FSW. Gametes were collected from the surface of these tanks and fertilized in separate 70-l tanks with FSW. After fertilization, embryos were gently rinsed three times by transferring to new containers and were subsequently transferred to 500-l tanks (containing 0.5-μm FSW) where they were kept through larval development. After 12 days, Symbiodinium-free coral larvae were collected using a 1 μm mesh net and washed three times in 0.2-μm FSW. Larvae were subsequently settled in sterile 6-well plates (8 plates per species, 40 larvae per well; each well filled with 10 ml of 0.2-μm FSW). Eight hours after settlement, the plates were separated between two temperature regimes: 4 plates per species were incubated at 27°C (control temperature), and the other 4 plates were ramped to 32°C over 5 h (thermal stress treatment); all plates were maintained in the dark (to prevent the growth of potential photosynthetic organisms). Settled juveniles were incubated at their respective temperature treatments and six random wells were sampled every 2 days. The size of the sampled juveniles was measured using a motorized stereomicroscope (Leica MZ16A, Leica Microsystems); sizes did not vary significantly between day 2 and day 6 with an average size of 0.79 mm² (±0.05) for A. millepora juveniles and of 0.82 mm² (±0.07) for A. tenuis juveniles.

qNMR analysis. After the required incubation time, seawater was removed from each well with a pipette, and a sterile cotton bud was used to soak up any residual seawater, taking care not to disturb the settled juvenile corals. Juveniles in six wells were extracted by adding 300 μl of deuterated methanol (CD₂OD) to each well, and 200 μl of gentle shaking. 200 μl of this extract was transferred into a 5-mm Bruker MATCH NMR tube and analysed immediately. In addition, negative control wells without settled juveniles were extracted following the same procedure. The concentrations of DMSP and acrylamide were normalized initially to the number of settled coral juveniles in the respective well. They were then normalized to the averaged surface area of the juveniles (note that juveniles were approximated to perfect circles).

DNA extractions and PCR amplification. At each time point, the contents of two wells were transferred into a 2-ml tube using a scalpel blade, snap frozen with liquid nitrogen, and used for total DNA extraction, according to methods in ref. 35. Multiplex sets of primers were subsequently used to target different taxonomic groups. SyntID1, coral11, and general primers for the algal 23S rRNA plastid and chloroplast DNA16 (Extended Data Table 1). Furthermore, three other DNA markers were used to target microbes: Bacteria16, Archaea16 and Fungi16 (Extended Data Table 1). The PCR consisted of 1 μl of DNA template (dilution series from 1 to 10⁻⁵ of the original concentrations), 10 μl of buffer containing dNTP and MgCl₂ (Bioline), 1.5 μl of each primer (10 μM), and 0.5 μl of Taq polymerase (Bioline), adjusted to a final volume of 50 μl with sterile MilliQ water. Amplified PCR products were visualized by electrophoresis on 1% agarose gel stained with ethidium bromide.

Clone libraries construction. PCR products from bacterial 16S ribosomal RNA gene were purified using a QIAquick gel extraction kit (QiaGen) according to the manufacturer’s instructions. Purified DNA was ligated into a TOPO-TO cloning vector (Invitrogen) and competent cells were transformed following the manufacturer’s instructions. Four samples, derived from the last experimental time point (6 days), were analysed (A. millepora at 27°C, A. millepora at 32°C, A. tenuis at 27°C, and A. tenuis at 32°C). A total of 48 clones were sequenced per sample (Macrogen Inc.) and chimaeric sequences were removed from subsequent analysis.
The nucleotide sequences obtained have been deposited in GenBank database under the accession numbers (KF619251 to KF619442).

Identification of candidate genes. Orthology between coral and diatom genes was inferred on the basis of best reciprocal BLAST hits. Orthologues in other species were identified using release 5 (March 2011) of the OrthoMCL database. Database for A. digitifera transcriptome: NCBI Transcriptome Shotgun Assembly (TSA).

Data analyses. Repeated measure ANOVA were performed on the normalized DMSP and acrylate concentrations (data met all assumptions of the test, except the acylate data from A. tenuis that violated sphericity assumption; in that unique case, Greenhouse–Geisser correction was applied to the degrees of freedom). Simple main effect tests were then used to compare the results from the temperature treatment within species (Extended Data Table 2).

Extended Data Figure 1 | Density and photosynthetic efficiency (mean ± s.e.) of Symbiodinium cells within adult colonies of the coral *Acropora millepora* maintained under control (27 °C) or thermal stress (32 °C) conditions for 10 days. a. Density of *Symbiodinium* cells in the same coral fragments through time. b. Comparison of photosystem II photochemical efficiency (maximum quantum yields $F_{v}/F_{m}$) through time (repeated measure ANOVA. *$P < 0.001$; post-hoc simple main effect test, *$P < 0.01$). See also Extended Data Table 3.
Extended Data Figure 2 | Representative transmission electron micrographs showing the effects of thermal stress on the internal structure of endosymbiotic Symbiodinium cells associated with the coral Acropora millepora. a, c, Symbiodinium cells after 10 days at 27 °C, showing intact cell structures (a) and intact thylakoid membranes of chloroplasts (arrows), the photosynthetic centre of cells (c). b, d, Symbiodinium cells after 10 days at 32 °C, showing structurally degraded cells (b) with highly disrupted thylakoid membranes (arrows) (d). Scale bars, 1 μm. ch, chloroplast; nu, nucleus.

e, Percentage of structurally damaged Symbiodinium cells within adult tissue throughout the thermal stress experiment. The numbers above the bars refer to the total number of Symbiodinium cells observed.
Extended Data Figure 3 | Phylogenetic distribution of the reductase and methyltransferase orthologues (OrthoMCL groups OG5_131390 and OG5_156314, respectively). Note the unusually sparse distribution of OG5_156314. In red: co-occurrence of these two enzymes occurs predominantly in DMSP-producing organisms. The only species of bacteria in the OrthoMCL database where these two enzymes occur simultaneously is the marine cyanobacterium *Synechococcus*.
Extended Data Table 1 | Primer pairs used to target the genomic DNA of various microorganisms possibly responsible for DMSP production to assess presence in coral juveniles

| Target organisms | Target region | Primer name | Amplicon size | Annealing temperature | Number of cycles | Reference | Amplification |
|------------------|---------------|-------------|---------------|-----------------------|------------------|-----------|--------------|
| Coral            | mtDNA         | RNS2/GR     | 700 bp        | 54°C                  | 30               | 36        | Yes          |

Data are presented at the genus level in per cent; 48 clones per sample. Bacteria previously implicated in the degradation of DMSP and DMS are shown in green and orange, respectively. Note the proportion of bacteria involved in DMS(P) degradation, representing 79.7% of the bacteria sequenced. References 43–52 are cited in this table.
