Supporting Information

ABSTRACT: The enzyme xanthine oxidoreductase (XOR) is an important source of oxygen free radicals and related postischemic injury. Xanthine dehydrogenase (XDH), the major form of XOR in tissues, can be converted to xanthine oxidase (XO) by oxidation of sulfhydryl residues or by proteolysis. The conversion of XDH to XO has been assumed to be required for radical generation and tissue injury. It is also possible that XDH could generate significant quantities of superoxide, \( \cdot \text{O}_2^- \), for cellular signaling or injury; however, this possibility and its potential ramifications have not been previously considered. To unambiguously determine if XDH can be a significant source of \( \cdot \text{O}_2^- \), experiments were performed to measure and characterize \( \cdot \text{O}_2^- \) generation using XDH from chicken liver that is locked in the dehydrogenase conformation. Electron paramagnetic resonance spin trapping experiments with 5-(diethoxyphosphoryl)-5-aminopropyl-N-oxide demonstrated that XDH in the presence of xanthine produces significant amounts of \( \cdot \text{O}_2^- \). NAD+ and NADH inhibited the generation of \( \cdot \text{O}_2^- \) from XDH in a dose-dependent manner, with NAD+ exhibiting stronger inhibition than NADH at low physiological concentrations. Decreased amounts of NAD+ and NADH, which occur during and following tissue ischemia, enhanced the generation of \( \cdot \text{O}_2^- \) from XDH in the presence of xanthine. It was observed that XDH-mediated oxygen radical generation markedly depressed \( \text{Ca}^{2+} \)-ATPase activity of isolated sarcoplasmic reticulum vesicles from cardiac muscle, and this was modulated by NAD+ and NADH. Thus, XDH can be an important redox-regulated source of \( \cdot \text{O}_2^- \) generation in ischemic tissue, and conversion to XO is not required to activate radical formation and subsequent tissue injury.

Mammalian xanthine dehydrogenase (XDH) is a dimeric protein with a molecular mass of 290 kDa that is composed of two identical independent subunits. Each subunit contains an N-terminal 20 kDa domain with two 2Fe–2S centers, a central 40 kDa flavin adenine dinucleotide (FAD) domain, and a C-terminal 85 kDa molybdopterin binding domain. Mammalian XDH can be readily converted to xanthine oxidase (XO) by oxidation of sulfhydryl residues or by proteolysis during extraction or purification procedures. Classically, XDH is considered to be NAD+ dependent, catalyzing the oxidative reaction of xanthine to urate with reduction of NAD+. XO also catalyzes urate formation but in a manner independent of NAD+, using O2 as an electron acceptor from the flavin site (Scheme 1). Therefore, XDH activity is considered primarily dependent on xanthine and NAD+, while XO is dependent on xanthine and O2. Over the past several decades, XO has been proposed to play a central role in the pathogenesis of oxidative injury in postischemic cells and tissues. In his seminal report, McCord proposed that ischemia activates free radical generation via a two-step process: (1) the requisite conversion of XDH to XO via a calcium-dependent protease and (2) the formation of the XO substrates hypoxanthine and xanthine secondary to the catabolism of ATP. This report triggered myriad biomedical studies in a variety of organ systems, including heart, lung, kidney, liver, and gastrointestinal tract, that have confirmed that XO plays an important role in the injury that occurs upon reperfusion of ischemic tissues. In this original report and all of the many biological and biomedical studies that have followed, the conversion of XDH to XO has been considered to be a requisite step for activation of oxygen free radical generation in postischemic tissues. Most of the xanthine oxidoreductase in mammalian cells is present in the form of XDH. Therefore, much attention has focused on the conversion of XDH to XO because this was considered as the critical first step leading to the formation of oxygen radicals.
In a series of studies applying EPR techniques to directly measure oxygen radical generation in reoxygenated endothelial cells and in cardiac models, it was observed that the process of radical generation was triggered primarily via the formation of the XO substrates hypoxanthine and xanthine due to ischemia-induced degradation of ATP.\textsuperscript{12–14} Little, if any, increase in the levels of XO occurred, and the magnitude and time course of radical generation precisely followed the cellular levels of XO substrates. Thus, it was reported that the levels of the substrates xanthine and hypoxanthine, not the formation of XO, are the key triggers activating postischemic radical generation.\textsuperscript{14}

In contrast to the hypothesis that conversion of XDH to XO is essential for oxygen radical formation, other researchers reported that XDH itself can reduce O2 with production of \( \text{•O}_2^- \) accompanying oxidation of xanthine.\textsuperscript{15–17} It was also reported that this oxygen-dependent XDH activity is influenced by NADH and NAD\textsuperscript{+}.\textsuperscript{3,15} In addition, oxidation of NADH by XDH also may produce \( \text{•O}_2^- \).\textsuperscript{15,16,18–20} Thus, controversy remains regarding whether XDH produces significant amounts of \( \text{•O}_2^- \) or whether the enzyme must first be converted to the oxidase form for this to occur.

XDH from chicken liver is locked in the dehydrogenase form and is not converted to XO; however, the enzyme is otherwise nonspecific to induce \( \text{•O}_2^- \) production.\textsuperscript{21} EPR spectroscopy with the use of spin traps allows measurement and quantitation of \( \text{•O}_2^- \) production in enzyme and cellular systems,\textsuperscript{22–24} and this has been facilitated by the development of the phosphorus-containing nitrore spin trap S-(diethoxyphosphoryl)-S-methyl-1-pyrroline-N-oxide (DEPMPO) that forms long-lived \( \text{•O}_2^- \) adducts.\textsuperscript{22,23} This procedure avoids the use of acetone extraction, thereby minimizing damage to the Mo center of this enzyme.\textsuperscript{24,31} XO (grade III, from buttermilk, chromatographically purified, in 2.3 M (NH\textsubscript{4})\textsubscript{2}SO\textsubscript{4} and 10 mM sodium phosphate buffer (pH 7.8) containing 1 mM EDTA and 1 mM sodium salicylate) was obtained from Sigma. The salicylate was removed chromatographically with Sephadex G-25 prior to use. Xanthine, NAD\textsuperscript{+}, and NADH were also obtained from Sigma. The spin trap S-(diethoxyphosphoryl)-S-methyl-1-pyrroline-N-oxide (DEPMPO) was purchased from Oxis.

**Spectrophotometric Measurements.** UV–visible absorption spectra of either XDH or XO and enzyme assays were performed with a Varian Cary 300 UV–visible spectrophotometer equipped with a temperature-controlled circulator. Xanthine-O2 activity was assayed in air-equilibrated PBS (pH 7.4) solutions at 25 °C after addition of xanthine (360 \( \mu \text{M} \)) by measurement of the production of uric acid from the change in absorbance at 295 nm (\( \varepsilon = 9500\text{ M}^{-1}\text{ cm}^{-1} \)). Xanthine-NAD\textsuperscript{+} activity was measured at 25 °C in PBS (pH 7.4) after addition of xanthine (360 \( \mu \text{M} \)) and NADH by measurement of the production of uric acid.

**EPR Measurements.** All EPR measurements were performed using Bruker ER 300 or ESP 300E spectrometers operating at X-band with TM\textsubscript{110} cavity resonators. The microwave frequency was measured with an EIP model 575 microwave counter (EIP Microwave, Inc., San Jose, CA). To assess \( \text{•O}_2^- \) generation, EPR spin trapping studies were performed using the spin trap DEPMPO.\textsuperscript{22,23} The following instrument settings were used in the spin trapping experiments: modulation amplitude, 0.32 G; microwave frequency was measured with an EIP model 575 microwave counter (EIP Microwave, Inc., San Jose, CA). To assess \( \text{•O}_2^- \) generation, EPR spin trapping studies were performed using the spin trap DEPMPO.\textsuperscript{22,23} The following instrument settings were used in the spin trapping experiments: modulation amplitude, 0.32 G; time constant, 0.16 s; scan time, 60 s; modulation frequency, 100 kHz; microwave power, 20 mW; microwave frequency, 9.76 GHz. The samples were placed in a quartz EPR flat cell, and spectra were recorded at ambient temperature (25 °C). The collection of EPR data was started 2 min after the addition of xanthine. The component signals observed in these spectra were identified and quantitated as reported. The double integrals of DEPMPO-OOH production in enzyme and cellular systems, the DEPMPO trapping efficiency was shown to be \( \sim 90\text{ M}^{-1}\text{ s}^{-1} \) at pH 7 and room temperature with a decay half-life of 890 s.\textsuperscript{25,26} In another study using both the riboflavin–light and xanthine–xanthine oxidase superoxide-generating systems, the DEPMPO trapping efficiency was shown to be \( \sim 65\% \) with 40-fold more sensitivity than the commonly used cytochrome c reduction method of superoxide detection.\textsuperscript{27} The cytochrome c reduction method has also been shown to be nonspecific in that cytochrome c can be reduced directly by reactive cysteines and by direct electron transfer from the redox-active centers of XDH and XO.\textsuperscript{28,29} Cytochrome c may also bind to XDH, slowing the rate of \( \text{•O}_2^- \) production.\textsuperscript{28} Thus, measurement of \( \text{•O}_2^- \) by DEPMPO spin trapping has the advantage of greater specificity and a lack of perturbation of XDH or XO. The unique stability and specificity of the DEPMPO \( \text{•O}_2^- \) spin trapping method makes it applicable to complex biochemical systems such as XO and XDH.

We performed a series of studies to definitively determine the presence and magnitude of the production of \( \text{•O}_2^- \) from purified chicken liver XDH in the presence of xanthine using EPR spin trapping. These measurements of \( \text{•O}_2^- \) production are correlated with spectrophotometric measurements of urate production. The concentration-dependent effects of NAD\textsuperscript{+} and NADH on this process are determined. Finally, measurements are performed to determine if the amount of \( \text{•O}_2^- \) production is related to tissue levels of XDH and xanthine is sufficient to induce oxidative injury of the critical Ca\textsuperscript{2+}-regulating ATPase pump of cardiac muscle, thus contributing to ischemia-reperfusion injury.
Sarcoplasmic Reticulum Preparation. Cardiac sarcoplasmic reticulum (SR) vesicles were isolated from the left ventricle of healthy, filarial free beagle dogs as follows.32–34 Dogs were anesthetized with sodium pentobarbital (25 mg/kg), and the heart was excised rapidly and placed in an ice-cold saline solution. Muscle (50 g) was minced and homogenized in imidazole buffer (pH 7) at 4 °C in an Excel autohomogenizer (DX-8, Nihon Seiki, Tokyo, Japan). The homogenate was centrifuged at 4000g for 20 min. The supernatant was then filtered through eight layers of cheesecloth and centrifuged at 10000g for 15 min. The supernatant was then filtered through eight layers of cheesecloth and centrifuged at 31000g for 15 min. The final pellet was resuspended in 30% sucrose and 10 mM imidazole (pH 7.0) to a nal concentration as determined by the method of Lowry et al. The isolated SR was stored at −80 °C until it was used.

Measurement of Ca²⁺-ATPase Activity. The Ca²⁺-ATPase activity of cardiac SR was determined as the rate at which inorganic phosphate (Pi) was liberated during the incubation. The incubation bath (5 mL) was kept at 37 °C and contained 100 mM KCl, 20 mM imidazole buffer (pH 7.0), 10 mM Na₂ATP, 5 mM MgCl₂, and 200 μM CaCl₂. The released phosphate in the filtrate was assayed by a colorimetric method.35 The Ca²⁺-ATPase activity was calculated as the difference in ATPase rate in a bath containing 200 μM Ca²⁺ compared to one containing 0.02 M EGTA.32–34,50,57

Statistical Analysis. All experiments were performed in triplicate and repeated at least three times. Results are expressed as means ± the standard error of the mean (SEM). Statistical analysis was performed by a Student’s t-test or a one-way analysis of variance. Significance was defined at the *p < 0.05 level.

RESULTS

Generation of *O₂⁻ from XDH Compared to XO. Initial experiments were performed to measure the magnitude of generation of *O₂⁻ from XDH in the presence of xanthine and to compare this to that from similar amounts of XO. Experiments were performed using the spin trap DEPMPO that provides a stable *O₂⁻ adduct.25 The DEPMPO was free of any background signal, and in the presence of XO or XDH alone, no signal was seen (Figure 1A,B, traces a and b). However, upon addition of xanthine to XO, a characteristic DEPMPO-OOH adduct spectrum was seen with hyperfine splitting giving rise to 12 resolved peaks (Figure 1A, trace c). In addition to the large signal of DEPMPO-OOH, a small signal of DEPMPO-OH was observed as reported previously.22,25 The *O₂⁻-derived DEPMPO-OOH adduct comprised 92% of the total intensity and the DEPMPO-OH adduct 8%. Upon addition of xanthine to XDH, a similar DEPMPO-OOH signal was observed; however, the intensity of this signal was approximately 40–50% lower than that seen with identical amounts of XO (Figure 1B, trace c). A large signal of DEPMPO-OOH comprising 80% of the total intensity and a small DEPMPO-OH component of 20% was observed. With both XO and XDH, these signals were quenched by SOD (150 units/mL), confirming that they were derived from *O₂⁻ (Figure 1A,B, trace d). The time course of *O₂⁻ generation was measured, and it was observed that over a period of 30 min both enzymes support a similar sustained process of *O₂⁻ generation (Figure 2A). In a series of repeat experiments, a similar process of *O₂⁻ generation was seen with the magnitude of generation by XDH being 55% of that of XO (Figure 2B). These data suggest that XDH can generate *O₂⁻ in the presence of xanthine in a manner similar to that with XO, although the magnitude is somewhat lower. A simulation of a
When NADH (0.1 mM) immediately followed by the addition of xanthine, a dose-dependent inhibition of xanthine-O₂− activity was observed (Table 1). Thus, both NADH and NAD+ inhibit the generation of *O₂− from XDH in the presence of xanthine, but NAD+ exhibits stronger inhibition at low (0.1−0.5 mM) physiological concentrations. With XO, however, NAD+ did not inhibit *O₂− generation even at >2 mM, while 2 mM NADH was required to reach just >50% inhibition.

Effects of NADH or NAD+ on the Generation of *O₂− from XDH and XO. Experiments were performed to investigate the effects of NADH and NAD+ on this XDH-mediated *O₂− generation. During ischemia, tissue xanthine14 and NADH38 levels are markedly increased compared to those in normally perfused tissues. Oxidation of NADH by XDH also could produce a significant amount of *O₂−. We examined the effects of NADH on the generation of *O₂− by XDH or XO. When NADH (0.1−1 mM) was added to XDH and this was immediately followed by addition of xanthine, a dose-dependent inhibition of *O₂− generation was observed (Figures 3A and 4A). Approximately 50 or 75% inhibition was seen with 0.1 or 0.5 mM NADH, respectively. In experiments when NAD+ (0.1−1 mM) was added to XDH immediately followed by addition of xanthine, a dose-dependent inhibition of *O₂− generation was observed (Figures 3B and 4B). Approximately 70 or 90% inhibition was seen with 0.1 or 0.5 mM NAD+, respectively.

We also measured the dose-dependent effects of NADH on the generation of *O₂− from XO. NADH clearly decreased the rate of *O₂− generation in a dose-dependent manner, but much higher levels were required with 50% inhibition seen only above 1 mM NADH (Table 1). The dose-dependent effects of NAD+ on the generation of *O₂− from XO were also measured, and it was observed that NAD+ did not inhibit the generation of *O₂− from XO (data not shown).

Thus, both NADH and NAD+ inhibit the generation of *O₂− from XDH in the presence of xanthine, but NAD+ exhibits stronger inhibition at low (0.1−0.5 mM) physiological concentrations. With XO, however, NAD+ did not inhibit *O₂− generation even at >2 mM, while 2 mM NADH was required to reach just >50% inhibition.

Effects of NADH on Xanthine-O₂ Activity. To determine if NADH inhibits not only *O₂− generation but also the conversion of xanthine to urate, we examined the effects of NADH on xanthine-O₂ activity of XDH and XO. When NADH (0.1−3 mM) was added to XDH and this was immediately followed by the addition of xanthine, a dose-dependent inhibition of xanthine-O₂ activity was observed (Table 2). With NADH concentrations of 2 mM, more than 50% inhibition was seen. The dose-dependent effects of NADH on the xanthine-O₂ activity of XO were also measured, and it was seen that NADH decreased xanthine-O₂ activity in a dose-dependent manner; however, much like the measurements of *O₂− generation, higher NADH levels were required to inhibit the activity of XO versus XDH (Table 1). Thus, these data demonstrate that NADH significantly depressed XDH- or XO-mediated *O₂− generation because of the inhibition of xanthine-O₂ activity.

Effects of NADH on Xanthine-NAD+ Activity. To further determine the dose-dependent effects of NADH on the conversion of xanthine to urate mediated by XDH in the...
presence of NAD⁺, the xanthine–NAD⁺ activity of XDH was measured. When NADH was added to XDH in the presence of NAD⁺ and this was immediately followed by the addition of xanthine, a dose-dependent inhibition of urate formation was observed (Table 2). These observations indicate that NADH inhibits XDH-mediated reduction of NAD⁺.

Effects of NAD⁺ on Xanthine–NAD⁺ Activity of XDH and XO. To correlate the effects of NAD⁺ on \( \text{O}_2^- \) generation with that on enzyme activity measured from the conversion of xanthine to urate, we examined the effects of NAD⁺ on the activity of XO and XDH. With XO, NAD⁺ levels of up to 2 mM did not alter XO activity as measured by urate formation. This is consistent with the role of O₂ as the requisite electron acceptor. With XDH, however, because NAD⁺ is the preferred substrate in the oxidative half-reaction, an increased level of uric acid formation was observed in accordance with the NAD⁺ concentration (Table 3).

### Table 1. Dose-Dependent Effects of NADH on \( \text{O}_2^- \) Generation and Xanthine-O₂ Activity of Xanthine Oxidase (XO)\(^a\)

| [NADH] (mM) | \( \text{O}_2^- \) generation (% of control) | % of initial xanthine-O₂ activity |
|------------|------------------------------------------|--------------------------------|
| 0.1        | 96.09 ± 3.91                             | 103.62 ± 3.26                   |
| 0.5        | 82.79 ± 2.61                             | 90.85 ± 8.89                    |
| 1.0        | 66.20 ± 2.04                             | 83.45 ± 4.47                    |
| 2.0        | 43.92 ± 2.14                             | 53.83 ± 3.45                     |
| 3.0        | 25.49 ± 2.36                             | 33.34 ± 5.25                     |

“NADH (0–3 mM) was added to XO (0.1 μM) as described in the legend of Figure 3. \( \text{O}_2^- \) generation was measured by EPR spin trapping using DEPMPO, and xanthine-O₂ activity was measured via a spectrophotometric assay of urate production monitored at 295 nm. Data are presented as means ± the standard error of triplicate experiments. \(^b\)Significantly different (\( p < 0.05 \)) from the corresponding control value.

### Table 2. Dose-Dependent Effects of NADH on the Activity of Xanthine Dehydrogenase (XDH)\(^a\)

| [NADH] (mM) | % of initial xanthine-O₂ activity | % of initial xanthine-NAD⁺ activity |
|-------------|---------------------------------|-----------------------------------|
| 0.1         | 75.3 ± 1.1\(^b\)               | 71.4 ± 3.6\(^c\)                  |
| 0.5         | 59.7 ± 0.8\(^b\)               | 51.0 ± 3.4\(^c\)                  |
| 1.0         | 51.2 ± 0.7\(^b\)               | 37.6 ± 4.8\(^c\)                  |
| 2.0         | 44.9 ± 1.1\(^b\)               | 22.3 ± 3.5\(^c\)                  |
| 3.0         | 23.8 ± 4.2\(^b\)               |                                    |

“NADH (0–3 mM) was added to XDH (0.1 μM) as described in the text. Xanthine-O₂ activity was measured from a spectrophotometric assay of urate production monitored at 295 nm. Xanthine-NAD⁺ activity, in the presence of NAD⁺ 0.5 mM, was measured by urate formation. Measurements were performed with addition of xanthine (360 μM) to the reaction mixture. Data are presented as means ± the standard error of triplicate experiments. \(^a\)Significantly different (\( p < 0.05 \)) from the corresponding control value. \(^b\)Significantly different (\( p < 0.05 \)) from the corresponding control value of the treated XDH–xanthine system (0.5 mM NAD⁺).

### Table 3. Dose-Dependent Effects of NAD⁺ on the Activity of Xanthine Dehydrogenase (XDH)\(^a\)

| [NAD⁺] (mM) | % of the maximal xanthine-NAD⁺ activity |
|------------|---------------------------------------|
| 0.0        | 13.0 ± 0.5                             |
| 0.1        | 39.5 ± 2.8\(^b\)                      |
| 0.3        | 83.9 ± 6.1\(^b\)                      |

| 2.0        | 100 ± 7.0\(^b\)                       |

“NAD⁺ (0–2 mM) was added to XDH (0.1 μM) as described in the text. Xanthine-NAD⁺ activity was measured from a spectrophotometric assay of urate production monitored at 295 nm. Measurements were performed with addition of xanthine (360 μM) to the reaction mixture. Data are presented as means ± the standard error of triplicate experiments. \(^a\)Significantly different (\( p < 0.05 \)) from the value in the absence of NAD⁺.

Effects of Oxygen Radicals Generated by the XDH–Xanthine System on Ca²⁺-ATPase Activity of Cardiac SR.

We and others have shown that the Ca²⁺-ATPase of SR is highly sensitive to oxidative damage.\(^{34,36,37}\) To determine if the process of XDH-mediated radical generation can be physiologically significant and to compare this to that from XO, we examined the effects of oxygen radicals generated from XDH or XO on Ca²⁺-ATPase activity of isolated SR from canine cardiac muscle. XO and XDH were used at a concentration of 0.1 μM, comparable to that measured in cardiac tissue, with xanthine levels of 360 μM similar to those formed in ischemic myocardium.\(^{35,39}\) Significant inhibition of Ca²⁺-ATPase activity was seen in both the XDH–xanthine system and the XO–xanthine system (Figure 5). We also measured the effects of NADH or NAD⁺ on XDH–xanthine-
mediated inhibition of Ca<sup>2+</sup>-ATPase activity. In the presence of either NADH or NAD<sup>+</sup>, only a modest decrease in the loss of Ca<sup>2+</sup>-ATPase activity was seen relative to that seen after adding only xanthine with significant inhibition in activity still remaining (Figure 5). These observations clearly suggested that oxygen radicals generated from XDH could cause the disruption of Ca<sup>2+</sup>-ATPase activity of cardiac SR in a manner similar to that seen with XO.

## DISCUSSION

Xanthine oxidoreductase (XOR) is a critical source of oxygen free radicals in biological cells and tissues and plays an important role in oxygen radical generation and the pathogenesis of injury following postischemic reperfusion. It has been demonstrated that XOR is critically important in the mechanism of postischemic radical generation; however, it was previously assumed that XOR inhibition from (XOR) was solely derived from the oxidase form with none arising from the dehydrogenase, which is typically more than 90% of the total XOR pool. This extends from the original proposal of McCord that the conversion of XDH to XO was required for oxygen radical generation. On this basis, attention over the last two decades has focused largely on conditions that convert XDH to XO in a manner similar to that of XO (Figures 1 and 2) and that this O<sub>2</sub>− generation can be modulated by the levels of NAD<sup>+</sup> and NADH (Figures 3 and 4).

In this study, EPR spin trapping measurements with the use of DEPMPO demonstrated the formation of the DEPMPO-O<sub>2</sub>− adduct that is specific for O<sub>2</sub>−. We assessed the quantity and time course of the production of O<sub>2</sub>− from XDH by comparing the relative rate of O<sub>2</sub>− production from XDH to that from XO, and we observed that the rate of O<sub>2</sub>− production from XDH was 55% of that from XO for the xanthine-O<sub>2</sub> reaction.

We observed that the production of O<sub>2</sub>− from XDH in the presence of xanthine was modulated by both NAD<sup>+</sup> and NADH, which exerted prominent concentration-dependent inhibition of O<sub>2</sub>− production. NAD+, however, exerted stronger inhibition at lower concentrations than that of NADH, as expected because of its effectiveness as an oxidant for XDH. Approximately 70 or 90% inhibition was seen with 0.1 or 0.5 mM NADH, respectively, while approximately 50 or 75% inhibition was seen with 0.1 or 0.5 mM NADH, respectively. This is in contrast to the inhibition seen with XO in the presence of xanthine that was affected by only NADH and not by NAD+ (Table 1). Even with 1 mM NADH, only approximately 30% inhibition of XO-derived O<sub>2</sub>− generation occurred. With XDH, however, 1 mM NADH or NAD+ induced >90 or >95% inhibition, respectively. Thus, for
cellular levels of the NAD⁺/NADH pool that are typically in the range of 0.1−0.5 mM,39 prominent dose-dependent inhibition of production of O₂⁻ from XDH was greater with NAD⁺ than NADH, while for XO, only modest inhibition was seen with only NADH and not with NAD⁺. The turnover numbers for the various reactivities of chicken liver XDH have been determined to be 102 min⁻¹ for the xanthine−NAD⁺ reductase reaction, 43 min⁻¹ for the xanthine−O₂ reductase reaction, and 2 min⁻¹ for the NADH−O₂ reductase reaction (pH 7.8 and 4 °C), which suggested that NADH or NAD⁺ binds near the reduced flavin, blocking access and thereby slowing its reactivity with O₂.46

It was also observed that NADH inhibited the activity of XDH measured from urate production in the presence of the substrate xanthine. This was true in the presence or absence of NAD⁺. This inhibition paralleled the observed decrease in *O₂⁻* production. Similarly, higher levels of NADH inhibited the activity of XO. This suggests that NADH associates with the FAD site of XDH or XO and competes with either NAD⁺ or O₂ for binding at this site, thus impeding electron transfer. While the inhibition observed in urate formation was also dose-dependent and largely paralleled that seen for *O₂⁻* production, in general this inhibition of activity was somewhat lower than that of *O₂⁻* production. Because XO or XDH can reduce O₂ to either *O₂⁻* or H₂O₂, this may suggest that NADH induces a shift to the two-electron reduction of O₂ to H₂O₂.50 It should also be noted that both XDH and XO have a NADH−O₂ reductase activity in which there is an obligatory two-electron reduction of the FAD center by NADH to give FADH₂.

The physiological or pathophysiological relevance of the modulation of *O₂⁻* generation and XDH function by NADH or NAD⁺ can be considered in view of the levels of NADH or NAD⁺ required to regulate the generation of *O₂⁻* from XDH. In normal tissues, the cellular concentrations of the NADH and NAD⁺ pool have been measured to be in the range of 0.25−0.5 mM.51 In normal oxygenated myocardium, most of the pool would be in the oxidized form as NAD⁺.49,52,53 However, with the marked hypoxia and reduced state during ischemia, the pool would be almost totally reduced.52 During ischemia, ATP is degraded to form the XO substrates hypoxanthine and xanthine.14 It has also been observed that the levels of the NADH and NAD⁺ pool are decreased by a factor of more than 2 over the first 40 min after reperfusion, and this has been attributed to the activation of the enzyme poly-ADPribose polymerase.49 Overall, the lower levels of the total pool and NAD⁺ in particular would enhance the production of *O₂⁻* from XDH. During ischemia, this would be limited by the O₂ levels in the myocardium, and *O₂⁻* generation would then be further stimulated with a prominent increase in the level of O₂ upon reperfusion.54

In the heart after ischemia for 30 min, intracellular concentrations of xanthine and hypoxanthine have been observed to increase from preischemic levels of <0.5 to 500−600 μM.14,59 The activity of XO in the ischemic heart has been measured to be ~10 milliuunits/g of protein and that of XDH to be ~130 milliuunits/g of protein.14,59 Thus, most of the XOR is in the reductase form. While after reperfusion we have previously observed a doubling in the levels of XO, still almost 90% of the enzyme remains in the form of XDH. The levels of XOR reported in the heart correspond to concentrations of ~0.1 μM.

We considered whether the levels of XDH and its substrates in the postischemic heart could result in sufficient radical generation to be functionally significant in the pathogenesis of myocardial injury. A hallmark of postischemic myocardial injury is an alteration in Ca²⁺ regulation due to oxidant-induced dysfunction of sarcoplasmic reticulum Ca²⁺-ATPase. We used this phenomenon to determine the effects of tissue levels of XDH in the presence of xanthine levels formed during myocardial ischemia. It was observed that the XDH-mediated oxygen radical generation markedly depressed Ca²⁺-ATPase activity (Figure 5). Furthermore, while 0.5 mM levels of either NAD⁺ or NADH lessened the degree of Ca²⁺-ATPase impairment, depressed activity was still apparent (Figure 5). This suggests that XDH-mediated oxidant injury of cardiac muscle does occur in postischemic tissues and that this process is modulated by the tissue levels of NADH and NAD⁺.

One can consider the effect of cellular redox state on the production of radicals from XOR. Overall, it was observed that the levels of NADH and NAD⁺ as well as their relative amount profoundly modulated the generation of *O₂⁻* from XDH (Figure 4). The production of *O₂⁻* by XDH was found to be redox-regulated with more production under reduced conditions with a higher proportion of the NAD(H) pool in the reduced state. An oxidant shift in the redox state with elevated NAD⁺ levels would decrease the level of generation of *O₂⁻* from XDH and perhaps serve as a feedback mechanism or brake to prevent oxidative injury from XO. However, major oxidant stress would induce the conversion of the reductase to the oxidase, which is unaffected by NAD⁺ and only modestly inhibited by higher levels of NADH. This may indicate that XDH, with its lower level and strongly NAD⁺-regulated *O₂⁻* generation, normally serves a signaling role that is tightly redox controlled, while under conditions of major oxidant stress conversion to XO removes this regulation, triggering higher levels of radical generation leading to cellular injury and death. Indeed, in postischemic myocardium, it is anticipated that the initial production of *O₂⁻* from XDH, which is enhanced by the reduced state of the myocardium and NAD⁺ depletion, could then trigger its subsequent partial conversion to XO.

In conclusion, our results indicate that XDH can be an important source of *O₂⁻* generation in cells and tissues. Its xanthine-mediated *O₂⁻* generation is regulated by the cellular levels of NAD(H) and the cellular redox state. Under normal conditions, XDH-mediated oxygen radical generation is redox-regulated and can serve a homeostatic role in cell signaling; however, under conditions of ischemia and reperfusion, this pathway is greatly enhanced and can lead to oxidative cellular injury with impaired calcium regulation. Because XDH is the predominant form of XOR in normal tissues, XDH-mediated *O₂⁻* generation can play an important role in cellular signaling and injury.
