ABSTRACT

As one of the brightest active blazars in both X-ray and very high energy \( \gamma \) -ray bands, Mrk 501, is very useful for physics associated with jets from active galactic nuclei. The ARGO-YBJ experiment has monitored Mrk 501 for \( \gamma \)-rays above 0.3 TeV since 2007 November. The largest flare since 2005 was observed from 2011 October and lasted until about 2012 April. In this paper, a detailed analysis of this event is reported. During the brightest \( \gamma \)-ray flaring episodes from 2011 October to November 22, an excess of the event rate over 6 \( \sigma \) is detected by ARGO-YBJ in the direction of Mrk 501, corresponding to an increase of the \( \gamma \)-ray flux above 1 TeV by a factor of 6.6 \( \pm \) 2.2 from its steady emission. In particular, the \( \gamma \)-ray flux above 8 TeV is detected with a significance better than 4\( \sigma \). Based on time-dependent synchrotron self-Compton (SSC) processes, the broadband energy spectrum is interpreted as the emission from an electron energy distribution parameterized with a single power-law function with an exponential cutoff at its high-energy end. The average spectral energy distribution for the steady emission is well described by this simple one-zone SSC model. However, the detection of \( \gamma \)-rays above 8 TeV during the flare challenges this model due to the hardness of the spectra. Correlations between X-rays and \( \gamma \)-rays are also investigated.

1. INTRODUCTION

Blazars, including BL Lac objects and flat-spectrum radio quasars, are the most extreme subclass of active galactic nuclei (AGNs). Most of the identified extragalactic \( \gamma \)-ray sources belong to this category. Their emission is believed to be dominated by non-thermal and strongly Doppler-boosted radiation from a relativistic jet of magnetized plasma which is aligned along our
line of sight. The physical mechanism for the production of their γ-ray emission is still under debate. Leptonic models attribute the γ-ray emission to inverse Compton scattering of the synchrotron (synchrotron self-Compton, SSC) or external photons (external Compton) by the same population of relativistic electrons (Ghisellini et al. 1998; Dermer et al. 1992; Sikora et al. 1994), therefore an X-ray/γ-ray correlation is expected. The lack of strong emission lines in the radiation from BL Lac objects is taken as evidence of ambient photons playing a minor role (e.g., Krawczynski 2004), and hence the SSC model is favored. Hadronic models attribute the γ-ray emission to proton-initiated cascades and/or proton–synchrotron emission in a magnetic field-dominated jet (Aharonian 2000). However, the tight X-ray and very high energy (VHE) γ-ray correlation and the very rapid γ-ray variability are taken as strong challenges to models based on hadronic processes. Recently, a long-term continuous monitoring of Mrk 421 has been performed based on the ARGO-YBJ experiment and satellite-borne X-ray detectors (Bartoli et al. 2011a). According to this investigation, both the temporal and the spectral results generally favor the SSC model. Even in the framework of the SSC model, the fundamental question referred to the origin of the flux and spectral variability, observed on timescales from minutes to tens of years, is still open to discussion.

Mrk 501 ($z = 0.034$) was discovered with VHE emission by the Whipple collaboration (Quinn et al. 1996). It is one of the best-studied blazars with extensive studies on various timescales. In 1997, Mrk 501 went into a state with surprisingly high activity and strong variability and became more than a factor of 10 brighter (above 1 TeV) than the Crab Nebula (Djannati-Atai et al. 1999; Aharonian et al. 1999; Amenomori et al. 2000). The fastest γ-ray flux variability on a timescale of minutes was observed in 2005 (Albert et al. 2007). Significant spectral variability was detected with the harder spectrum at timescales of seconds to minutes requiring the number of fired pads ($N_{\text{pad}}$) to be at least 20 within 420 ns on the entire carpet. The trigger rate is 3.5 kHz with a dead time of 4%. The angular resolution, pointing accuracy, and stability of the ARGO-YBJ detector array have been thoroughly characterized (Bartoli et al. 2011b). The absolute energy scale uncertainty is less than 13% for all measured cosmic-ray showers (Bartoli et al. 2011b). More details about the detector and the RPC performance can be found in Aielli et al. (2006, 2009a, 2009b, 2009c).

For the multi-wavelength investigation together with Fermi-LAT, the data collected by ARGO-YBJ after 2008 August when Fermi was launched are used. The total effective observation time is 1179.6 days. To achieve a good angular resolution, events with zenith angles less than 50° are used, and further selection criteria (Bartoli et al. 2011a, 2012) are applied. The total number of events after filtering is $1.86 \times 10^{11}$ for this work. No γ/hadron discrimination is applied. The opening angle $\psi_{70}$, which contains 71.5% of the events from a point-like source, is 1.36 for events with $N_{\text{pad}} > 60$. In order to remove the effect of the cosmic-ray anisotropy, the method described in Bartoli et al. (2011a, 2012) was applied. The significance of the excess is estimated using the Li & Ma (1983) method. With this data analysis, the significance of the excess observed from the direction of the Crab Nebula is 17 standard deviations ($\sigma$) in 3.5 years, which indicates that the 3.5 year cumulative $5\sigma$ sensitivity of ARGO-YBJ has reached 0.3 Crab for point sources (Cao & Chen 2011).

3. RESULTS

3.1. Light Curves

The daily flux from Mrk 501 at energy 15–50 keV provided by Swift/BAT24 is publicly available and used in this work. The light curve from 2008 August to 2012 April is shown in panel (a) of Figure 1 with a bin size of 30 days. The best fit with a constant value for the light curve is $(8.9 \pm 0.4) \times 10^{-4}$ counts cm$^{-2}$ s$^{-1}$ with a $\chi^2$ of 492.9 for 44 degrees of freedom (ndf). A significant feature is the flare at the end of 2011 with the flux enhanced by a factor of about four. Without data during the flaring periods.

24 Transient monitor results provided by the Swift/BAT team: http://heasarc.gsfc.nasa.gov/docs/swift/results/transients/weak/Mrk501/.
period, the best fit with a constant value for the light curve is $(6.0 \pm 0.4) \times 10^{-4}$ counts cm$^{-2}$ s$^{-1}$ with a $\chi^2$/ndf of 69.3/38. This result could be evidence for small X-ray variability before this flaring period. Looking at a close-up view of the Swift/BAT light curve at 15–50 keV shown in Figure 2, the large flare began on 2011 October 17 (MJD = 55851) and decreased to a low-activity state around the average level on November 22 (MJD = 55887; hereafter flare 1). Afterward, Mrk 501 became increasingly active for a longer period until about 2012 April. Its brightest flaring episode was on 2011 November 8, during the flare 1 period.

The Fermi-LAT data were analyzed using ScienceTools. The light curve was generated using aperture photometry. Panel (b) of Figure 1 shows the flux at energies greater than 0.3 GeV that is contained within a 2° cone centered on Mrk 501, which is the 68% containment angle of the reconstructed incoming photon direction for normal incidence. A fit with a constant value yields a $\chi^2$/ndf of 107.7/44 indicating a moderately variable behavior consistent with the X-ray analysis. The discrete correlation function (DCF), computed as prescribed by Edelson & Krolik (1988), for the BAT/LAT data points shown in Figure 1 is $DCF = 0.63 \pm 0.26$ for a time lag of zero, which is greater than the previously measured $DCF = 0.32 \pm 0.22$ (Abdo et al. 2011). Since the significance in both analyses is less than 2.5σ, only minor correlations are observed. During the X-ray flaring period, the GeV $\gamma$-ray flux increased above the long-term average, but this flux increase is not significant. Therefore, the light curve does not indicate a significant correlation with the X-ray data during the flare.

The light curve in the TeV $\gamma$-ray range detected by ARGO-YBJ is shown in panel (c) of Figure 1. During the X-ray flare, the flux of TeV $\gamma$-rays also increases. A fit with a constant emitting rate yields a $\chi^2$/ndf of 71.9/44, while the $\chi^2$/ndf is reduced to 42.59/38 simply by excluding the data during the X-ray flares. The TeV $\gamma$-ray flare 1 was clearly detected as a

---

http://fermi.gsfc.nasa.gov/ssc/
counterpart of that in the X-ray band, and the count rate increase is by a factor of about six. The DCF for the BAT/ARGO-YBJ data points shown in Figure 1 is $0.85 \pm 0.36$ for a time lag of zero, while the DCF for the LAT/ARGO-YBJ is $0.44 \pm 0.31$.

### 3.2. Photon Energy Spectra

To investigate the evolution of the spectra, their time averages during the long-term quasi-steady state from 2008 August 5 to 2011 October 16 and during flare 1 are estimated separately. The integrated flux from Mrk 501 observed by ARGO-YBJ has a statistical significance of $5\sigma$ (see panel (a) of Figure 3). During flare 1, the flux from Mrk 501 was detected by ARGO-YBJ with a $6.1\sigma$ significance (see panel (b) of Figure 3), corresponding to an increase of the $\gamma$-ray flux above 1 TeV by a factor of 6.6 from its steady emission. Events with $N_{\text{pad}} > 60$ are used for both panels of Figure 3. For comparison, all of the spectra are shown in Figure 6, where an average spectrum over 4.5 months was adapted from Abdo et al. (2011). Since no significant activity was observed in the three years prior to flare 1, the average spectra over 4.5 months could approximately represent the average spectra over three years. All the other spectra presented in Figure 6 are estimated as follows.

#### 3.2.1. Swift: X-Ray

The Swift/XRT is a focusing X-ray telescope with an energy range from 0.2 to 10 keV. In Windowed Timing mode during flare 1, XRT data in four time windows are available from HEASARC, and the exposure time is about 1 ks.

---

26 http://heasarc.gsfc.nasa.gov/
in each window. The XRT data set was processed with the XRTDAS software package (v.2.6.0) following the standard recommendations. The XRT average spectrum in the 0.5–10 keV energy band was fitted using the XSPEC package (v.12.7.0). We adopted a power-law model for the photon-flux spectral density, with an absorption hydrogen-equivalent column density fixed to the Galactic value in the direction of the source, namely $1.56 \times 10^{20}$ cm$^{-2}$ (Kalberla et al. 2005). We obtain the spectrum of $(0.0407 \pm 0.0007) \times (E/1$ keV)$^{-1.824 \pm 0.022}$ photon cm$^{-2}$ s$^{-1}$ keV$^{-1}$.

3.2.2. Fermi-LAT: HE $\gamma$-Rays

The LAT data from a region centered on Mrk 501 with a radius of 10$^\circ$ were used to estimate the spectrum. The data analysis was performed following the standard recommendations by using an unbinned maximum-likelihood method to estimate the source SED. We adopted a power-law model for the energy range from 0.1 to 300 GeV. During the long-term period, Mrk 501 was detected with a test statistic (TS) value of 5118.2 ($\sim$3.1σ). We obtain the spectrum $(3.30 \pm 0.68) \times 10^{-10} (E/1844.3$ MeV)$^{-1.774 \pm 0.021}$ photon cm$^{-2}$ s$^{-1}$ MeV$^{-1}$. This is consistent with the result reported by the LAT collaboration using the data collected during the first 24 months (Abdo et al. 2010). The spectrum was found to be very stable in the GeV band despite a moderate variability over a long period. During flare 1, the TS was 329.1 ($\sim$18.1σ) and the spectrum was $(3.53 \pm 0.46) \times 10^{-10} (E/1844.3$ MeV)$^{-1.640 \pm 0.084}$ photon cm$^{-2}$ s$^{-1}$ MeV$^{-1}$. Compared with the long-term result, the flux increased slightly.

3.2.3. ARGO-YBJ: VHE $\gamma$-Rays

The VHE $\gamma$-ray spectrum was estimated using a distribution of the excess in the number of events as a function of $N_{\text{had}}$. We follow a widely used procedure, which is described in Bartoli et al. (2011a). In this procedure, the spectrum of Mrk 501 is assumed to be a power law. The ARGO-YBJ detector response has been taken into account using G4argo (Guo et al. 2010). The simulated events are sampled in the energy range from 10 GeV to 100 TeV. We define six intervals with $N_{\text{had}}$ of 20–59, 60–99, 100–199, 200–499, 500–999, and $\geq$1000. The best fit gives a differential flux (cm$^{-2}$ s$^{-1}$ TeV$^{-1}$)

$$(1.92 \pm 0.44) \times 10^{-12} \left(\frac{E}{2$ TeV}$\right)^{-2.59 \pm 0.27}$$

for the long-term period, corresponding to $0.312 \pm 0.076$ Crab above 1 TeV. The median energies of the six intervals are 0.45, 0.89, 1.4, 2.8, 5.6, and 11 TeV, respectively. Both the flux and the spectral index are similar to those obtained by VERITAS and MAGIC during the low-activity state, as presented in Abdo et al. (2011). In particular, the ARGO-YBJ data show a smooth extension of the Fermi-LAT results, as evident in Figure 6. During flare 1, the differential flux (cm$^{-2}$ s$^{-1}$ TeV$^{-1}$) is

$$(2.92 \pm 0.52) \times 10^{-12} \left(\frac{E}{4$ TeV}$\right)^{-2.07 \pm 0.21}$$

(2)

corresponding to $2.05 \pm 0.48$ Crab above 1 TeV, which is a factor of 6.6 $\pm$ 2.2 compared with its long-term steady state. The median energies of the six intervals are 0.89, 1.1, 1.8, 3.5, 7.1, and 14 TeV, respectively. Only the statistical error is quoted here, and the systematic uncertainty in the flux measurement is estimated to be $\leq 30\%$ (Aielli et al. 2010).

4. DISCUSSION

4.1. Spectra Corrected for Extragalactic Background Light Absorption

During flare 1, $\gamma$-rays with a median energy of 8.4 TeV are also observed with a significance greater than $4\sigma$, as shown in Figure 4. $\gamma$-rays with such a high energy from Mrk 501 have not been detected since the 1997 flare. The SED at energies above 0.9 TeV is harder than those observed during the flares in 1997 (Aharonian et al. 2001) and in the 2005 June 30 flare (Albert et al. 2007), as shown in Figure 6, although the spectral indices are consistent if the statistical error is taken into account. Mrk 501 is a nearby source, so we do not expect a significant absorption of its intrinsic source spectrum due to extragalactic background light (EBL) at energies below 1 TeV, while the absorption at higher energies is still considerable. Therefore, it is useful to test different EBL models assuming a minimum intrinsic photon spectral index. A natural minimum spectral index is 1.64, constrained by the spectrum in the GeV band, since that should be steeper at higher energies.

Here we use four kinds of models with different flux levels of the EBL, among many models. Assuming a single power law for the VHE flux, the indices of the derived unabsorbed spectra using different models are (1) $1.80^{+0.26}_{-0.29}$ for the “low-IR” model proposed by Kneiske et al. (2004), which gives a result similar to that obtained using the EBL model of Aharonian et al. (2006), according to Albert et al. (2007), (2) $1.45^{+0.30}_{-0.42}$ for the model of Franceschini et al. (2008), which is widely used to correct the VHE SED of extragalactic sources, (3) and (4) $1.30^{+0.34}_{-0.38}$ and $1.11^{+0.37}_{-0.41}$ for the baseline and fast evolution models proposed by Stecker et al. (2006, 2007), respectively. For comparison, all of the unabsorbed spectra are shown in Figure 5. The spectral indices obtained using models (2)–(4) exceed the minimum spectral index boundary of 1.64; however, they are consistent with this limit if the statistical error is taken into account. Note that models (3) and (4) have been excluded with higher significance by previous tests carried out around 1 TeV (Aharonian et al. 2006; Georganopoulos et al. 2010) and tens of GeV (Abdo et al. 2009, 2010). Since our data extend to about 10 TeV, the corresponding EBL photon energy is substantially lower. The EBL model with minimum absorption is used when modeling the SED in the following section.

4.2. Modeling of the Overall SED

The long-term averaged SED, especially the continuous measurement of the second component in the energy range 0.1 GeV–10 TeV obtained in this work, provides a robust baseline for insight into the underlying physics of Mrk 501. Over the very wide radio–VHE energy range, we fitted a one-zone SSC model proposed by Mastichiadis & Kirk (1995; see also Mastichiadis & Kirk 1997; Yang et al. 2008) to the SED. There are a few free parameters to be determined in this model, including the Doppler factor $\delta = 1/|1-c^2\beta^2|$, the spherical blob radius $R$, the magnetic field strength $B$, the electron spectral index $s$, the electron maximum Lorentz factor $\gamma_{\text{max}}$, and the electron injection compactness $I_s = 1/3 m_e c^2 R^2 \int_{1}^{\infty} d\gamma (\gamma-1) Q_\gamma$. In order to determine the Doppler factor and the injection compactness, further parameters must be determined, i.e., the Lorentz factor $\Gamma$, the speed of the blob $\beta$, and the Lorentz factor of electrons $\gamma$. Moreover, $\sigma_t$ is the Thomson cross section, $\theta$ is the angle between the direction of motion of the blob and the observer’s line of sight, and $Q_\gamma$ is the electron spectrum at injection, which is assumed to be a power-law cutoff at $\gamma_{\text{max}}$, with a
Figure 4. Significance map of the Mrk 501 region during the flaring period from MJD 55851 to 55887. Events with $N_{pad} > 500$ are used, whose corresponding median energy is 8.4 TeV.

(A color version of this figure is available in the online journal.)

Figure 5. Spectra of Mrk 501 during the flaring period from MJD 55851 to 55887. The spectrum from 0.1 GeV to 300 GeV is observed by Fermi-LAT. The solid line is the fit to the Fermi-LAT data using a power law. The spectrum observed by ARGO-YBJ has been corrected for EBL absorption using four different EBL models. Details can be found in the text.

(A color version of this figure is available in the online journal.)

normalization factor $q_e$, $Q_e = q_e \gamma^{-s} \exp(-\gamma / \gamma_{max})$. This model is different from other one-zone SSC models which introduce more free parameters using stationary injected electron spectra with a double power-law function (Tavecchio et al. 2001; Anderhub et al. 2009) or even triple power-law function (Abdo et al. 2011) with an exponential cutoff at the high-energy end. A full time-dependent evolution of the electron and photon spectra based on this model was simulated for a given injection spectrum of electrons. The low-IR model proposed by Kneiske et al. (2004) is used to take into account the absorption of $\gamma$-rays in the EBL when modeling the SED.

The best fit to the long-term SED is shown in Figure 6, with the corresponding parameters given in Table 1. General agreement between the model and the data is achieved with this

Bartoli et al.

Figure 6. Spectral energy distribution of Mrk 501. The solid lines show the best fits to the data with a one-zone SSC model, with the best-fit parameters listed in Table 1. The black curve corresponds to an SED model describing the long-term averaged data, while the red curve describes the flaring data. (A color version of this figure is available in the online journal.)

Table 1

| Flux Level | $\gamma_{\text{max}}$ | $l_e$ | $B$ (G) | $R$ (cm) | $\delta$ | $s$ |
|------------|-----------------------|-------|---------|---------|---------|-----|
| Long-term  | $3 \times 10^6$       | $1.8 \times 10^{-5}$ | 0.07    | $3 \times 10^{16}$ | 12 | 1.95 |
| Flare 1    | $8 \times 10^6$       | $8 \times 10^{-5}$   | 0.10    | $1 \times 10^{16}$ | 10 | 1.6  |

simple one-zone SSC model. The parameters in the model are found in general agreement with those found in the previous analysis on the similar source Mrk 421 (Bartoli et al. 2011a). The best fit for flare 1 is also shown in Figure 6, with the corresponding parameters given in Table 1. The highest-energy data points of the SED (>6 TeV) during flare 1 cannot be well reproduced by only modifying the parameters. It is important to point out that the X-ray spectrum becomes harder during the flare. The peak energy is shifted to about 10 keV during flare 1 from about 1 keV in the quasi-steady state. The shift of the X/$\gamma$-ray peak to higher energies during flares is a common feature that has been reported many times (e.g., Albert et al. 2007; Anderhub et al. 2009; Acciari et al. 2011). However, the detection of >6 TeV $\gamma$-rays with an energy flux similar to that at 1 TeV is unusual. In the framework of the SSC model, it is difficult to reproduce such high-energy $\gamma$-rays as detected by ARGO-YBJ. Since the $\gamma$-rays above 1 TeV are typically produced in the Klein–Nishina regime, their rate should be strongly suppressed. The radiation mechanism during flares may be different from that in the quasi-steady state. Different radiation mechanisms, such as more complex SSC models or hadronic processes (e.g., in Abramowski et al. 2012), are needed to improve the understanding of the flaring phenomena.

5. SUMMARY

We have presented continuous long-term monitoring of Mrk 501 from 2008 August to 2012 April. Both the flux and the spectral index are consistent with those obtained by VERITAS and MAGIC during a 4.5 month multi-frequency campaign (Abdo et al. 2011). Combining the observations by the ARGO-YBJ experiment with the space-borne experiments with Swift and Fermi, the investigation was performed over a wide energy range from 0.5 keV up to 10 TeV (a value higher than the maximum in Abdo et al. 2011). Using all the data covering various energy bands during the quasi-steady phase of the blazar, its SED is fitted with a simple one-zone SSC model assuming a single power law with exponential cutoff for the electron spectrum at injection. The model parameters are found to be in agreement with those resulting from previous analyses for various AGNs, indicating that similar radiation mechanisms are in action. A strong flare of the blazar in the VHE region was observed by ARGO-YBJ in 2011 October, while no Cherenkov Telescope observations of Mrk 501 were possible during this period. It is well determined to be a counterpart of the X-ray flare in the same time period, giving for the BAT/ARGO-YBJ data points a DCF of $0.85 \pm 0.36$ for a time lag of zero. On the contrary, there is no significant increase of the flux at energies around 1 GeV. Remarkably, $\gamma$-rays with energies above 8 TeV are detected, which has not happened since the 1997 flare. The spectral shape obtained with the data in the GeV/TeV energy region during the flare favors the “low-IR” EBL model of Kneiske et al. (2004), while a simple one-zone SSC model with a single power-law electron spectrum at injection is not able to reproduce the spectral shape at the highest energies (above 6 TeV).

This work is supported in China by the NSFC (grant No. 10120130794), the Chinese Ministry of Science and Technology, the Chinese Academy of Sciences, the Key Laboratory of Particle Astrophysics, CAS, and in Italy by the Istituto Nazionale di Fisica Nucleare (INFN).

We are grateful to Yupeng Chen for his help in estimating the X-ray spectrum using the Swift/XRT data. We also acknowledge essential support from W. Y. Chen, G. Yang, X. F. Yuan, C. Y.
