ABSTRACT

A growing body of work uses the paradigm of algorithmic fairness to frame the development of techniques to anticipate and proactively mitigate the introduction or exacerbation of health inequities that may follow from the use of model-guided decision-making. We evaluate the interplay between measures of model performance, fairness, and the expected utility of decision-making to offer practical recommendations for the operationalization of algorithmic fairness principles for the development and evaluation of predictive models in healthcare. We conduct an empirical case-study via development of models to estimate the ten-year risk of atherosclerotic cardiovascular disease to inform statin initiation in accordance with clinical practice guidelines. We demonstrate that approaches that incorporate fairness considerations into the model training objective typically do not improve model performance or confer greater net benefit for any of the studied patient populations compared to the use of standard learning paradigms followed by threshold selection concordant with patient preferences, evidence of intervention effectiveness, and model calibration. These results hold when the measured outcomes are not subject to differential measurement error across patient populations and threshold selection is unconstrained, regardless of whether differences in model performance metrics, such as in true and false positive error rates, are present. In closing, we argue for focusing model development efforts on developing calibrated models that predict outcomes well for all patient populations while emphasizing that such efforts are complementary to transparent reporting, participatory design, and reasoning about the impact of model-informed interventions in context.

1 INTRODUCTION

The use of machine learning to guide clinical decision-making and resource allocation can introduce or perpetuate inequities in care access and quality, ultimately contributing to health disparities [64, 97]. Aiming to detect and mitigate such harms, recent works leverage the algorithmic fairness paradigm [10] to define evaluation criteria and model development procedures that quantify and constrain the magnitude of statistical differences in model behavior or performance across patient subgroups [8, 9, 19, 22, 67, 70, 74, 81, 82, 108]. Within this paradigm, numerous criteria, metrics, and algorithms have been proposed, and both major and minor incompatibilities and trade-offs among them have been identified [21, 25, 32, 51, 53, 71].

The purpose of this work is to synthesize, contextualize, and validate underappreciated limitations of the algorithmic fairness paradigm to contribute to the development of best practices for appropriately operationalizing algorithmic fairness principles in healthcare [99]. We do so in a setting where observational data stored in an electronic health records or claims database is used to fit a patient-level predictive model for a clinical outcome where the score output by the model informs the allocation of a clinical...
intervention, typically through comparison of the score to a decision threshold. For our analysis, we assume that the observed outcomes are not subject to unobserved differential measurement error across patient subgroups [45, 64], that the choice of decision threshold used to allocate a clinical intervention on the basis of the output of a predictive model is not constrained by resource or operational constraints [47], and that the values embedded in the data collection and problem formulation processes are transparently reported and reflect those of the patient populations affected by the use of the model [12, 18, 33, 60, 68, 80].

For the development of predictive models to inform clinical decision-making, we argue for aiming to maximize the expected utility that the model-informed intervention confers to each patient subgroup of interest. The notion of expected utility that we consider depends on the values and preferences of affected stakeholders and can be quantified in terms of the expected costs or utilities associated with false positive and false negative errors in binary classification settings or in terms of the expected benefits and harms of the intervention conditioned on risk in more general settings [86, 96]. We hypothesize that, in practice, model development strategies that nominally promote fairness, by constraining for parity in model performance metrics across subgroups or by maximizing worst-case model performance over subgroups, do not confer greater expected utility for any patient subgroup than the approach of identifying a set of calibrated models that predict the outcome well for each subgroup, followed by threshold selection reflecting the contextual assessment of the benefits and harms of the intervention. The key observations motivating this hypothesis are detailed in section 2 and largely follow directly from related work [7, 25, 32, 51, 53, 71, 72, 83, 86, 94–96, 102].

We evaluate our hypothesis through a case study of estimators of the risk of atherosclerotic cardiovascular disease (ASCVD) within ten years to inform the initiation of cholesterol-lowering statin therapy [3, 35, 38, 54, 87]. We conduct experiments to assess which model development strategies confer maximal expected utility for subgroups defined in terms of race, ethnicity, sex, or co-morbidities (type 1 and type 2 diabetes, chronic kidney disease (CKD), or rheumatoid arthritis (RA)). We compare pooled and stratified unconstrained empirical risk minimization (ERM) to regularized fairness objectives and distributionally robust optimization (DRO) objectives that aim to minimize differences in or improve the worst-case area under the receiver operating characteristic curve (AUC) or log-loss across subgroups. We further conduct an analysis to investigate the impact of constraints on differences in true and false positive rates. To evaluate the utility that the model confers, we use the notion of net benefit [94, 96] to define normalized expected utility measures that parameterize the relative value of the harms and benefits of statin initiation on the basis of decision thresholds recommended by clinical practice guidelines. To evaluate net benefit in this setting, we adopt the assumption that the intervention induces constant relative risk reduction (section 3.3).

2 BACKGROUND AND PROBLEM FORMULATION

2.1 Supervised learning for binary outcomes and algorithmic fairness

Here, we introduce the formal notation and key assumptions used throughout the work. Let \( X \in \mathbb{R}^m \) be a variable designating a vector of covariates and \( Y \in \mathcal{Y} = \{0, 1\} \) be a binary indicator of an outcome. We consider data that may be partitioned on the basis of a discrete indicator of a categorical attribute \( A \in \mathcal{A} = \{A_k\}_{k=1}^K \) with \( K \) categories. In some cases, \( A \) may correspond to an attribute that describes partitions of the population, where the value of \( A = A_k \) refers to a specific partition defined by the attribute. Examples of attributes used to partition the population include demographic attributes (e.g. race, ethnicity, gender, sex, age subgroup) or strata defined by complex clinical phenotypes or comorbidity profiles. We use the shorthand \( D_{A_k} \), when referring to the subset corresponding to the subgroup \( A_k \).

The objective of supervised learning with binary outcomes is to use data \( D = \{(x_i, y_i, a_i)\}_{i=1}^N \sim P(X, Y, A) \) to learn a function \( f_\theta : \mathbb{R}^m \rightarrow [0, 1] \) parameterized by \( \theta \). The function \( f_\theta \) can be considered to be a risk estimator that, when optimal, estimates \( \mathbb{E}[Y \mid X] = P(Y = 1 \mid X) \). We designate the random variable resulting from the application of the model \( f_\theta \) to \( X \) to be given \( S \), such that \( S = f_\theta(X) \). Given \( S \), a predictor \( \hat{Y} \) may be derived by comparing \( S \) to a threshold \( \tau_y \in [0, 1] \) to produce binary predictions \( \hat{Y}(X) = \mathbb{1}[f_\theta(X) \geq \tau_y] \in \{0, 1\} \).

The calibration curve \( c : [0, 1] \rightarrow [0, 1] \) is defined as a function that describes the expected value of \( Y \) given \( S \), such that \( c(s) = \mathbb{E}[Y \mid S = s] = P(Y = 1 \mid S = s) \). A model is said to be calibrated if \( c(s) = s \) for all \( s \). The calibration curve can be used to assess the extent to which a model over or underestimates the risk of the outcome \( Y \). For instance, if \( c(s') > s' \) then the observed event rate for the set of patients with scores of \( s' \) is greater than \( s' \), implying that the model underestimates risk for patients with scores of \( s' \).

Assessments of algorithmic fairness rely on fairness criteria, i.e. statistical properties reflecting moral or normative judgements as to the principles that constitute fairness. A broad class of fairness criteria can be described in terms of metric parity \((g_f(\cdot) \perp A)\), which requires that one or more metrics \( g_f : \mathcal{F} \times (X, Y) \rightarrow \mathbb{R} \) be equal across the subgroups defined by \( A \). Common instantiations of metric parity include equalized odds \( (\hat{Y} \perp \perp A \mid Y \text{ or } S \perp \perp \perp A \mid Y) \) [39], which requires both the true positive rates and the false positive rates to be equal across subgroups, demographic parity \( (\hat{Y} \perp \perp A \text{ or } S \perp \perp A) \) [16], which requires the rate at which patients are classified as belonging to the positive class is equal across subgroups, predictive parity \( (Y \perp \perp A \mid S \perp \perp A \mid Y = 1) \) [21], which requires parity in the positive predictive values, as well as criteria defined over other performance metrics [17, 27], including the AUC [13, 63] or the average log-loss or empirical risk [100]. Another important class of fairness criteria is defined over the calibration curve. Within that class, we focus on the sufficiency condition \((Y \perp \perp A \mid S)\) [10, 53], which requires the calibration curves for each subgroup be equal, and the group calibration condition \((\mathbb{E}[Y \mid S = s, A = a] = s)\) [51, 73], which requires the model to be calibrated for each subgroup.
2.2 Assessing the utility and net benefit of decision-making at a threshold

To contextualize the presentation of algorithmic fairness, we present a utility-theoretic perspective on clinical decision-making. For this framing, we consider a decision rule that implies intervention allocation on the basis of a binary predictor \( \hat{Y}(X) = 1 \) \( f_\theta(X) \geq \tau_g \).

We define \( U^{\text{cond}}(s) = U^{\text{cond}}_c(s) - U^{\text{cond}}_0(s) \) as the conditional expected utility of the decision rule, where \( U^{\text{cond}}_c(s) \) designates the expected utility associated with treating patients whose predicted scores \( S = f_\theta(X) \) are \( s \), and \( U^{\text{cond}}_0(s) \) is the expected utility of not treating patients whose scores are \( s \). We define the aggregate expected utility \( U^{\text{agg}}(\tau_y) \) of the decision to be the average utility over the population, given that the intervention is allocated for all patients with scores at or above the threshold \( \tau_y \):

\[
U^{\text{agg}}(\tau_y) = \mathbb{E}[U^{\text{cond}}_c | S \geq \tau_y]P(S \geq \tau_y) + \mathbb{E}[U^{\text{cond}}_0 | S < \tau_y]P(S < \tau_y).
\]

The optimal decision rule for a fixed predictive model is one where the intervention is allocated to patients with scores for which \( U^{\text{cond}}(s) > 0 \) and not allocated to those for which \( U^{\text{cond}}(s) < 0 \). If \( U^{\text{cond}}(s) \) is strictly monotonically increasing in \( s \) and has a root in \([0, 1]\), then the optimal threshold \( \tau_y^* \) is given by the point at which \( U^{\text{cond}}(s = \tau_y^*) = 0 \). When \( U^{\text{cond}}(s) \) is strictly monotonic but has no root in \([0, 1]\), then either the treat-all \( (\tau_y = 0) \) or treat-none \( (\tau_y = 1) \) strategies are optimal.

In some cases, \( U^{\text{cond}}(s) \) can be written as a simple function of the calibration curve. For example, if the costs and benefits of decision-making can be written as fixed expected costs or utilities of true positive (\( u_{TP} \)), false positive (\( u_{FP} \)), true negative (\( u_{TN} \)), and false negative (\( u_{FN} \)) classification, then \( U^{\text{cond}}(s) = (u_{TP} - u_{FN})c(s) + (u_{FP} - u_{TN})(1 - c(s)) \) and the optimal threshold is given by \([25, 86]\):

\[
\tau_y^* = c^{-1}\left(\frac{u_{TP} - u_{FN}}{u_{TN} - u_{FP} + u_{TP} - u_{FN}}\right).
\]

It follows that when a model is calibrated, the optimal threshold is given by \( \tau_y^* = \frac{MN - MF}{TN - FN + TN - FN} \), when the model is miscalibrated, but the calibration curve is strictly monotonic, the optimal threshold is given by the point at which the calibration curve intersects \( \tau_y^* \). Furthermore, given the relationship between the \( c(s) \) and \( U^{\text{cond}}(s) \), monotonicity in the calibration curve implies monotonicity in the conditional utility, and setting a threshold on the basis of the calibration curve can be interpreted as setting a threshold on \( U^{\text{cond}}(s) \).

To assess the expected utility of the decision rule over a population, it is typically not necessary to evaluate \( U^{\text{agg}}(\tau_y) \) with equation (1). Instead, a chosen decision threshold can be used to parameterize the net benefit \([94, 96]\) of the decision rule under the assumption that the chosen threshold is optimal, for a calibrated model, based on the values of the decision maker and the effectiveness of the intervention. The net benefit under the assumption of fixed costs or utilities of classification errors is given by \([94, 96]\):

\[
\text{NB}(\tau_y; \tau_y^*) = P(S \geq \tau_y | Y = 1)P(Y = 1) \]
\[
- P(S \geq \tau_y | Y = 0)P(Y = 0),
\]

where \( \tau_y \) is the evaluated decision threshold and \( \tau_y^* \) parameterizes the net benefit. This metric is fundamental to decision curve analysis \([94, 96]\), as a decision curve is the curve that results from evaluating net benefit for a range of thresholds for which \( \tau_y = \tau_y^* \). Both the net benefit and \( U^{\text{agg}}(\tau_y) \) are maximized at the threshold that results from the application of equation (2) when the assumptions outlined above are met.

We introduce the notion of the calibrated net benefit (cNB) to assess the net benefit under the assumption that the decision threshold used is adjusted on the basis of observed miscalibration. If \( c(s) \) is the calibration curve, then the calibrated net benefit evaluated at a threshold \( \tau_y \) is given by the net benefit evaluated at a threshold \( \tau_y^* = c^{-1}(\tau_y) \) on the score \( S \). The calibrated net benefit under the assumption of fixed classification costs is given by

\[
\text{cNB}(\tau_y; \tau_y^*) = P(S \geq c^{-1}(\tau_y) | Y = 1)P(Y = 1) \]
\[
- P(S \geq c^{-1}(\tau_y) | Y = 0)P(Y = 0),
\]

where \( \tau_y \) is the evaluated decision threshold and \( \tau_y^* \) parameterizes the net benefit. This metric is fundamental to decision curve analysis \([94, 96]\), as a decision curve is the curve that results from evaluating net benefit for a range of thresholds for which \( \tau_y = \tau_y^* \). Both the net benefit and \( U^{\text{agg}}(\tau_y) \) are maximized at the threshold that results from the application of equation (2) when the assumptions outlined above are met.

2.3 Implications for algorithmic fairness

A key consequence of the analysis presented thus far is that, subject to the assumptions detailed in section 2.2, the optimal threshold rule applied to a predictive model that outputs a continuous-valued risk score is based directly on the calibration characteristics of the model and the assumed expected costs or utilities of classification errors that encapsulate the effectiveness of the intervention and the preferences for downstream benefits and harms. As has been argued in related work \([7, 24, 25, 32]\), it follows that if the model is calibrated for each subgroup, the decision threshold that maximizes expected utility and net benefit for each subgroup is the same when the expected utilities associated with each classification error do not change across subgroups. We verify this claim in simulation in supplementary section A1 (Supplementary Figure A1). Furthermore, in this case, sufficiency implies that the use of a consistent threshold on the risk score for all subgroups corresponds to the use of a consistent threshold on the conditional utility \( U^{\text{cond}}(s) \) across subgroups, corresponding to an intuitive notion of fairness even in the case that the chosen decision threshold is not necessarily optimal \([7, 25]\). However, we note that this can still be a misleading notion of fairness given that it does not account for heterogeneity in the outcome not accounted for by the model under consideration \([25]\).

As is described in prior work \([21, 25, 51, 53, 83]\), one should expect models that minimize the empirical risk for the population overall, with respect to a data distribution containing features \( X \) that encode \( A \) to be calibrated overall and for each patient subgroup but to violate equalized odds, demographic parity, and predictive parity when such models exhibit differences across subgroups in the distribution of the risk score \( S \) or when the prevalence or incidence of the outcome \( Y \) differs across subgroups. Consequently, approaches undertaken to constrain the model training objective \([2, 17, 26, 27, 71, 105]\) to minimize violation of fairness criteria such as equalized odds or demographic parity typically reduce utility through some combination of explicit threshold adjustment \([39]\) towards a threshold unrelated to the one selected on the basis of preference solicitation in the context of the intervention, induced
miscalibration that analogously implies decision-making at a threshold unrelated to the utility-maximizing one [32], or reduction in model fit [71]. Given the relationship between the calibration curve and the conditional utility described in section 2.2, induced miscalibration that results in sufficiency violation implies that the use of a consistent threshold on the score across subgroups results in the use of different thresholds on $U_{\text{cond}}$ across subgroups.

2.4 Algorithmic fairness training objectives

In our experiments, we evaluate training objectives that incorporate algorithmic fairness goals and constraints into their specification. We do so not to advocate for the use of their use, but rather to develop evidence as to the extent to which theoretical properties and trade-offs manifest empirically. We focus our efforts on "in-processing" approaches [2, 17, 26, 27, 105] rather than on pre- [43, 55, 56, 84, 106] or post-processing [10, 39] (e.g., threshold-adjustment) approaches because in-processing approaches are well-suited to learning models that achieve the minimum achievable trade-off between measures of model performance and fairness in practical finite-sample settings [101] and further allow for exploration of smooth trade-offs induced by relaxation of the constraint [2, 27]. We specifically focus on scalable gradient-based learning procedures that use regularized objectives to penalize violation of fairness criteria in a minibatch setting, to enable the use of these procedures for deep neural network models learned with large-scale datasets. We also investigate approaches that, rather than constraining for parity in a metric across subgroups, attempts to improve the worst-case value of the metric over subgroups using distributionally robust optimization (DRO) [20, 30, 58, 72, 79].

Following Pfohl et al. [71], the regularized training objective is ERM that incorporates a non-negative penalty term $R$ that assesses the extent to which a fairness criterion of interest is violated and a non-negative parameter $\lambda$ that may be tuned to control the extent to which violation of the criteria is penalized:

$$
\min_{\theta \in \Theta} \sum_{i=1}^{N} w_i \ell(y_i, f_\theta(x_i)) + \lambda R,
$$

where $w_i$ are sample weights. In our experiments, we use this formulation to penalize violation of equalized odds and differences in AUC and log-loss across subgroups. To penalize violation of equalized odds, we primarily use a term that penalizes the maximization to penalize violation of equalized odds and differences in the AUC or log-loss between each subgroup with the overall population equalized odds, we primarily use a term that penalizes the maximization to penalize violation of equalized odds and differences in the AUC or log-loss across subgroups. To penalize violation of the criteria is provided in supplementary section A.4.

Beyond regularized objectives for algorithmic fairness, we evaluate distributionally robust optimization (DRO) developed in Pfohl et al. [72] and extended in Pfohl et al. [72]. The algorithm is implemented as the following alternating updates conducted over minibatches:

$$
\lambda_k \leftarrow \lambda_k \exp \left( \eta g(\theta_0, D_{A_k}) \right) / \sum_{k=1}^{K} \exp \left( \eta g(\theta_0, D_{A_k}) \right)
$$

and

$$
\min_{\theta \in \Theta} \sum_{k=1}^{K} \lambda_k \sum_{i=1}^{n_k} w_i \ell(y_i, f_\theta(x_i)),
$$

where $\eta$ is a non-negative scalar hyperparameter, $\{\lambda_k\}_{k=1}^{K}$ are non-negative scalars that sum to 1, and $g$ is a performance metric where lower values of the metric indicate better performance. In our experiments, we evaluate the use of the log-loss and 1 − AUC as the choice of metric $g$, as in Pfohl et al. [72].

3 CASE STUDY IN ATHEROSCLEROTIC DISEASE RISK ESTIMATION

3.1 Background on ASCVD risk estimation for statin initiation

Clinical practice guidelines for the primary prevention of cardiovascular disease recommend the use of estimates of ten-year atherosclerotic cardiovascular disease (ASCVD) risk to inform the initiation of cholesterol-lowering statin therapy [3, 35, 38, 54, 87]. These guidelines primarily recommend the use of risk estimates provided by the Pooled Cohort Equations [35] and its extensions [104]. However, these estimates have been reported to systematically over-estimate or under-estimate risk in ways that are consequential for the appropriateness of downstream treatment decisions. This miscalibration has been reported to occur both overall [23, 28, 69, 75] and for subgroups defined on the basis of race/ethnicity [1, 29, 48], sex [23, 28, 62], socioeconomic status [54], or for patients with comorbidities which influence ASCVD risk or the expected benefit and harms of statin therapy, including diabetes [1, 75], chronic kidney disease (CKD) [1, 40, 46], and rheumatoid arthritis (RA) [66, 92]. Approaches undertaken to address these issues include the development of new risk estimators from large, diverse observational cohorts using modern machine learning methods [49, 70, 98, 104, 107], revisions to guidelines to encourage follow-up testing when the benefits of statin therapy are unclear and shared patient-clinician decision-making to incorporate patient preferences and other context [54], and the incorporation of fairness constraints into the model development process [9, 32, 70].
3.2 Supervised learning with censored binary outcomes

To address systematic censoring of ten-year ASCVD outcomes, we adopt an inverse probability of censoring weighting (IPCW) approach during model training and evaluation [14, 44, 61, 78, 91, 93]. Intuitively, the appropriate weights scale with the probability of remaining uncensored at the earliest of the ASCVD event time, the censoring time, and the ten-year follow up horizon. In our experiments, we use flexible neural network models in discrete time, such as those described in Kvamme and Borgan [52], to estimate a conditional model for the censoring survival function. A technical specification of the problem formulation and assumptions necessary to motivate the IPCW approach is provided in supplementary section A.2. In supplementary section A.4, we extend each of the metrics used for evaluation and as components of the training objectives presented in section 2.4 to account for censoring by incorporating IPCW weights.

3.3 Assessing net benefit in terms of risk reduction

For the evaluation of models that predict the risk of ASCVD to inform statin initiation, we introduce an alternative formulation of the net benefit that is defined in terms of the population absolute risk reduction after subtracting out harms represented on the same scale. We use the guideline-concordant thresholds of 7.5% and 20%, which correspond to the bounds of the intermediate and high-risk categories, respectively in clinical practice guidelines [3, 35, 54]. We do so to parameterize the net benefit in terms of clinically-plausible benefit-harm trade-offs. Here, we summarize the key aspects of the formulation, but include a full derivation in supplementary section A.3.

For this case, the relevant utilities are defined by the absence \( u^s_y \) and presence \( u^s_y \) of an ASCVD event within ten years. The expected event rates conditioned on the score \( s \) are given by \( p^y_y(s) \) and \( p^0_y(s) \) in the absence and presence of treatment, respectively. The conditional absolute risk reduction is given by \( \text{ARR}(s) = p^0_y(s) - p^1_y(s) \). We assume that the expected harm of the intervention can be represented as a constant \( k_{\text{harm}} \) that is independent of the risk estimate. With these assumptions, \( U_\text{cond}(s) = (u^y_y - u^0_y) \text{ARR}(s) - k_{\text{harm}} \) and the optimal threshold is given by \( \tau_y^* = \text{ARR}^{-1}(\frac{k_{\text{harm}}}{u^y_y - u^0_y}) \).

We further assume that the intervention induces constant relative risk reduction, such that \( \text{ARR}(s) = r(s) \) for a constant \( r \in (0, 1) \) and the conditional expected utility and optimal threshold are simple transformations of the calibration curve, as was the case for the fixed-cost setting. In this case, \( U_\text{cond}(s) = (u^y_y - u^0_y)r(s) - k_{\text{harm}} \) and \( \tau_y^* = e^{-1}(\frac{k_{\text{harm}}}{r(u^y_y - u^0_y)}) \). We derive a formulation of the net benefit in this setting as

\[
\begin{align*}
NB(\tau_y; \tau_y^*) &= -(1 - \text{NPV}(\tau_y))P(S < \tau_y) \\
&\quad - P(S \geq \tau_y)(1 - r)\text{PPV}(\tau_y) + r\tau_y^* + P(Y = 1),
\end{align*}
\]

where \( \text{NPV}(\tau_y) \) and \( \text{PPV}(\tau_y) \) are the negative and positive predictive values evaluated at a threshold \( \tau_y \). The calibrated net benefit is defined analogously in equation (26).

To operationalize this notion of net benefit, as a proof-of-concept, we use a simple model for the treatment effect of statin initiation presented in Soran et al. [85]. Using that model and the properties of our cohort, we derive a constant value of 27.5% for the expected ten-year relative risk reduction following from moderate-intensity statin initiation (supplementary section A.5).

3.4 Cohort definition

All data are derived from Optum’s de-identified ClInformatics® Data Mart Database (Optum CDM), a statistically de-identified large commercial and medicare advantage claims database containing records from 2007 to 2019. We utilize version 8.1 of the database mapped to the Observational Medical Outcomes Partnership Common Data Model (OMOP CDM) version 5.3.1 [41, 57, 77]. Approval for the use of this data for this study was granted by the Stanford Institutional Review Board protocol #46829. Individuals wishing to access the data used in this work may sign a data use agreement with Stanford and Optum to access the data for replication or confirmatory studies on the Stanford Secure Data Ecosystem.

We apply criteria to extract a cohort for learning estimators of ten-year ASCVD risk that mirrors the population eligible for risk-based allocation of statins based on clinical practice guidelines [3]. The characteristics of the extracted cohort are provided in Supplementary Table B1. We consider as candidate index events all office visits and outpatient encounters for patients between 40 and 75 years of age at the time of the visit for patients without a prior statin prescription or history of cardiovascular disease (Supplementary Table B2). We restrict the set of candidate index events to those recorded as occurring at or before December 31, 2008 for which at least one year of historical data is available, and randomly sample one of the resulting candidate index events per patient for inclusion in the final cohort.

The times of ASCVD and censoring events are identified relative to the index event dates. ASCVD events are defined as the occurrence of a diagnosis code for myocardial infarction, stroke, or fatal coronary heart disease (Supplementary Table B2). We consider coronary heart disease to be fatal if death occurs within a year of the recording of the diagnosis code. Censoring events are identified as the earliest date of statin prescription (Supplementary Table B2), death, or the end of the latest enrollment period. From the extracted ASCVD and censoring times, we construct composite binary outcomes and censoring indicators at ten years, following the logic of supplementary section A.2.

3.4.1 Subgroup definitions. We define discrete subgroups on the basis of (1) a combined race and ethnicity variable based on reported racial and ethnic categories, (2) patient sex, (3) intersectional categories describing intersections of racial and ethnic categories with sex, (4) history of either type 2 diabetes, type 1 diabetes, RA, or CKD at the index date. To construct the race and ethnicity attribute, we assign “Hispanic or Latino” if the recorded OMOP CDM concept for ethnicity is recorded as "Hispanic or Latino", and the value of the recorded OMOP CDM racial category otherwise. This resulted in a final categorization of “Asian”, “Black or African American”,...
“Hispanic or Latino”, “Other”, and “White”, which we shortened to “Asian”, “Black”, “Hispanic”, “Other”, and “White” for succinctness in the presentation of the results. We identify patients with a history of type 2 diabetes, type 1 diabetes, rheumatoid arthritis, or chronic kidney disease using the presence of a concept identifier indicative of the condition recorded prior to the index date (Supplementary Table B2). The selected concept identifiers used for identifying type 2 and type 1 diabetes are adapted from Reps and Rijnbeek [76]; those used to identify chronic kidney disease are adapted from Suchard et al. [88].

3.5 Experiments

Here, we provide an overview of the experiments and defer a detailed description to supplementary section A.6. As in Pfohl et al. [72], we extract a set of clinical features to use an input to fully-connected feedforward neural networks and logistic regression models using observation of unique OMOP CDM concepts recorded prior to each patient’s selected index date (supplementary section A.6.1). The cohort is partitioned following the strategy described in supplementary section A.6.2. We use the procedures described in supplementary section A.6.3 to derive IPCW weights appropriate for estimating the risk of ASCVD within ten years using neural networks trained with the discrete-time likelihood [34, 52, 90] to estimate the censoring survival function conditioned on the full set of features used to fit the model for ten-year ASCVD. We make all experimental code available at https://github.com/som-shahlab/net_benefit_ascvd.

To serve as baseline comparators for all experiments, we train models using unconstrained IPCW-weighted ERM without stratification (pooled ERM; supplementary section A.6.4). The first experiment aims to evaluate strategies to learn models that predict the outcome well for subgroups defined following stratification by race, ethnicity, and sex, including intersectional categories, and for patients with ASCVD-promoting comorbidities. To compare with pooled ERM, we evaluate models trained with ERM separately on each subgroup (stratified ERM), models trained with IPCW-weighted regularized training objectives that penalize differences in the log-loss or AUC between each subgroup and the overall population, and IPCW-weighted DRO objectives that target the worst-case log-loss or AUC across subgroups (supplementary section A.6.5). The second experiment aims to assess the implications of penalizing violation of the equalized odds criterion across subgroups defined on the basis of race, ethnicity, and sex (supplementary section A.6.6). To evaluate the effect of penalizing violation of equalized odds, we use regularized training objectives that incorporate an IPCW-weighted MMD penalty to penalize differences in the outcome-conditioned distribution of the risk score between each subgroup and the marginal population (equations (27) and (29)), as well as a penalty that penalizes differences in the true positive and false negative rates between each subgroup and the marginal population at the guideline-relevant thresholds of 7.5% and 20% [3] using an IPCW-weighted objective that uses a softplus relaxation to the indicator function (equation (30)).

A detailed description of the evaluation procedure is described in supplementary section A.6.7. In brief, we assess model performance in the test set in terms of IPCW-weighted variants of the AUC, the average log-loss, the absolute calibration error (ACE) [4, 71, 103], true positive rate, false positive rate, calibration curve, and the net benefit (using the formulation of section 3.3). Estimates of the calibration curve used to calculate ACE and the calibrated net benefit rely on an IPCW-weighted logistic regression estimator trained on the held-out data to predict the outcome using logit-transformed outputs of the predictive model as inputs. The inverse of the calibration curve used to compute the calibrated net benefit is derived analytically based on the coefficients of the learned logistic regression model. Confidence intervals are generated with the percentile bootstrap with 1,000 iterations. Confidence intervals for the difference in performance for a comparator relative to pooled ERM are generated based on the bootstrap distribution of differences computed on the same bootstrap samples.

4 RESULTS

4.1 Approaches to improve model performance over subgroups

We conducted an experiment to assess whether approaches that penalize differences in AUC or log-loss across subgroups or optimize for the worst-case value of these metrics improve upon empirical risk minimization approaches in terms of the model performance and net benefit measures. In the main text, we report the results assessed relative to those derived from unpenalized ERM applied to the entire population for subgroups defined in terms of race, ethnicity, and sex (Figure 1; results for intersectional subgroups included in Supplementary Figure C3), as well as for subgroups with ASCVD-promoting comorbidities (Supplementary Figure C5). Absolute performance estimates are reported in the supplementary material (Supplementary Figure C6 and Supplementary Figure C7).

We find that the use of unconstrained empirical risk minimization using data from the entire population typically results in models with the greatest AUC for each subgroup, but stratified ERM procedures that train a separate model for each subgroup achieve an AUC that does not differ substantially in some cases, particularly for majority subgroups (Figure 1D and Supplementary Figure C5D,E,F). The models trained with regularized fairness objectives or DRO and selected on the basis of the worst-case AUC or log-loss do not improve on the AUC assessed for each subgroup, and typically perform substantially worse, with the least extreme degradation observed for those models trained with the AUC-based DRO training objective (Figure 1C,D and Supplementary Figure C5C,D,E,F). Despite the lack of improvement in AUC, we observe that subgroup-specific ERM and both regularized and DRO-based objectives that incorporate the AUC into their training objective often result in improved model calibration for some subgroups (1E,F,G,H and Supplementary Figure C5G,I,J,K,L). Similarly, subgroup-specific training does result in minor improvements in the log-loss for some subgroups relative to ERM applied to the entire population, but these results are typically observed only for larger subgroups when they are present (Figure 1K,L and Supplementary Figure C5Q,R).

The implication of these effects can be understood holistically through an assessment of the net benefit of statin therapy initiated on the basis of the risk estimates. As before, we report relative
Figure 1: The performance of models that estimate ten-year ASCVD risk, stratified by race, ethnicity, and sex, relative to the results attained by the application of unpenalized ERM to the overall population. Results shown are the relative AUC, absolute calibration error (ACE), and log-loss assessed in the overall population, on each subgroup, and in the worst-case over subgroups following the application of unconstrained pooled or stratified ERM, regularized objectives that penalize differences in the log-loss or AUC across subgroups, or DRO objectives that optimize for the worst-case log-loss or AUC across subgroups. Error bars indicate 95% confidence intervals derived with the percentile bootstrap with 1,000 iterations.

(Figure 2, Supplementary Figures C4 and C9) and absolute estimates (Supplementary Figures C8 and C10). Overall, no approach consistently confers more net benefit than unpenalized ERM applied to the entire population for each subgroup, when the net benefit is assessed for the benefit-harm trade-offs corresponding to either of the thresholds of 7.5% or 20%, but subgroup-specific training and AUC-based DRO approaches do lead to minor improvements in some cases (Figure 2C,D,K,L and Supplementary Figure C9,C,F,O,R). However, we note that, for each subgroup, no approach improves on the calibrated net benefit, i.e. the net benefit achieved following adjustment of the decision threshold to account for the observed miscalibration, relative to unpenalized ERM applied to the entire population (Figure 2G,H,O,P and Supplementary Figure C9,J,K,L,UV,W,X). This indicates that for those cases where an alternative strategy results in an increase in the net benefit conferred relative to that which is achieved for the pooled ERM strategy, it is a consequence of the improvement in calibration at the threshold of interest.

4.2 Regularized fairness objectives for equalized odds

We further conducted an experiment to assess the implications of the use of a training objective that penalizes violation of equalized odds across intersectional subgroups defined by race, ethnicity, and sex. In the main text, we present the results corresponding to an MMD-based penalty evaluated over subgroups defined by race and ethnicity, but include in the supplementary material analogous results corresponding to evaluation over intersectional categories and for sex (Supplementary Figures C15 to C28). Furthermore, the supplementary material includes analogous results for experiments that penalize equalized odds at both of the thresholds of 7.5% and 20% using softplus relaxations of the true positive and false positive rates (Supplementary Figures C29 to C49).

We observe that as the strength of the penalty \( \lambda \) increases, the AUC assessed for each subgroup monotonically decreases (Figure 3A,D). With a minor degree of equalized-odds promoting regularization (i.e. \( \lambda = 0.01,0.0562 \), calibration actually improves relative to the result for unpenalized ERM (Figure 3C,F) and there is little to no change in the log-loss for each subgroup despite the reduction in AUC (Figure 3B,E). This is reflected in the calibration curves presented in Figure 4, where we observe modest miscalibration consistent with overestimation of risk for each subgroup for the unconstrained model (Figure 4A) with improvements in the calibration of the model with a minor degree of regularization (Figure 4B,C). However, for large degrees of regularization (i.e. \( \lambda = 1.78 \) and \( \lambda = 10 \)), both the calibration and log-loss assessed for each subgroup deteriorate, although the reduction in AUC remains modest (Figure 3). In this case, the variability in the risk estimates sharply decreases to concentrate around the incidence of the outcome for larger degrees of regularization, which is reflected in the shape of the calibration curve and error rates as a function of the threshold (Figure 4F,L,R), consistent with overestimation for patients with
Figure 2: The net benefit of models that estimate ten-year ASCVD risk, stratified by race, ethnicity, and sex, relative to the results attained by the application of unpenalized ERM to the overall population. Results shown are the net benefit (NB) and calibrated net benefit (cNB), parameterized by the choice of a decision threshold of 7.5% or 20%, assessed in the overall population, on each subgroup, and in the worst-case over subgroups following the application of unconstrained pooled or stratified ERM, regularized objectives that penalize differences in the log-loss or AUC across subgroups, or DRO objectives that optimize for the worst-case log-loss or AUC across subgroups. Error bars indicate 95% confidence intervals derived with the percentile bootstrap with 1,000 iterations.

For the unconstrained model, the true positive rates and false positive rates at each threshold are ranked across subgroups in accordance with the observed incidence for each subgroup, such that the Black population has the largest true positive rate and false positive rate while the Asian population has the lowest true positive rate and false positive rate (Figure 4G,H). The regularized training objective is successful at enforcing the equalized odds constraint, in that the variability in false positive and true positives rates trends towards zero as the strength of the penalty increases (Figures 4 and Supplementary Figure C11).

For the benefit-harm trade-off implied by the use of either a threshold of 7.5% or 20%, we observe clear reductions in net benefit for each subgroup for large values of $\lambda$ (Figure 5A,C,E,G). With minor amounts of regularization, we observe little to no reduction in net benefit parameterized by either a threshold of 7.5% or 20%, and the point estimates for 20% even suggest a relative increase in net benefit compared to unpenalized ERM (Figure 5E,G). However, for large degrees of regularization, we observe large reductions in net benefit relative to that which is attained from unpenalized ERM, but the magnitude of these differences are attenuated when the thresholds applied for each subgroup are adjusted to account for miscalibration (Figure 5B,D,F,H). We further observe that the calibrated net benefit for equalized odds penalized models does not improve on unpenalized ERM at any value of $\lambda$ (Figure 5C,F,D,H). Overall, the reduction in net benefit observed directly due to operating at a suboptimal decision threshold, as a result of miscalibration, is generally larger than the reduction in net benefit that results due to the reduction in the AUC of the model at larger values of $\lambda$. Furthermore, we note that threshold adjustment to recover net benefit lost due to the miscalibration resulting from the use of the training objective that penalizes equalized odds violation does not preserve the satisfaction of the equalized odds fairness constraint.
Figure 3: Model performance evaluated across racial and ethnic subgroups for models trained with an objective that penalizes violation of equalized odds across intersectional subgroups defined on the basis of race, ethnicity, and sex using a MMD-based penalty. Plotted, for each subgroup and value of the regularization parameter $\lambda$, is the area under the receiver operating characteristic curve (AUC), log-loss, and absolute calibration error (ACE). Relative results are reported relative to those attained for unconstrained empirical risk minimization. Error bars indicate 95% confidence intervals derived with the percentile bootstrap with 1,000 iterations.

Figure 4: Calibration curves, true positive rates, and false positive rates evaluated for a range of thresholds across racial and ethnic subgroups for models trained with an objective that penalizes violation of equalized odds across intersectional subgroups defined on the basis of race, ethnicity, and sex using a MMD-based penalty. Plotted, for each subgroup and value of the regularization parameter $\lambda$, are the calibration curve (incidence), true positive rate (TPR), and false positive rate (FPR) as a function of the decision threshold. Error bands indicate 95% confidence intervals derived with the percentile bootstrap with 1,000 iterations.

As the variability in error rates at the adjusted thresholds is observed to be similar to or more variable than that which results from unpenalized ERM (Supplementary Figure C11).

To gain further insight into these phenomena, we plot the net benefit for a range of decision thresholds, assuming that the benefit-harm trade-off is fixed to one implied by the use of a threshold of 7.5% (Supplementary Figure C12). We also include analogous results for the threshold of 20% (Supplementary Figure C13), as well as standard decisions curves defined such that the net benefit plotted for each point on the curve corresponds to the benefit-harm trade-off implied by the corresponding threshold on the x-axis (Supplementary Figure C14). As expected for the analysis corresponding to
a threshold of 7.5%, the calibrated net benefit is maximized for each subgroup at a threshold on the risk estimates corresponding to the point where the observed incidence of the outcome conditioned on the risk estimate is 7.5% (Supplementary Figure C12M,N,O,P,Q,R). Furthermore, when the model overestimates risk at a threshold of 7.5% due to miscalibration, such as was the case for the unpenalized ERM model and for the models trained with a large penalty on equalized odds violation, the threshold that maximizes the net benefit is one greater than 7.5% (Supplementary Figure C12A,D,E,F). In these cases, adjusting the threshold on the penalized models to compensate for miscalibration recovers the majority of difference in net benefit relative to the model derived with unpenalized ERM.

5 DISCUSSION

This work has implications for the operationalization of algorithmic fairness in healthcare. We argue that assessment of fairness in terms of the equalized odds, demographic parity, or predictive parity criteria are likely to be misleading in cases where the incidence of the outcome differs across groups because differences in those metrics are expected when decision-making maximizes net benefit for each subgroup by developing a well-fitting, calibrated model for each subgroup and setting a decision threshold on the basis of model calibration and preferences for downstream benefits and harms of the decision. For predictive models that estimate the risk of ASCVD, our experiments evaluate a variety of model development approaches, including those that penalize violation of equalized odds, and find no evidence that any alternative improves on empirical risk minimization applied to the entire population, due to either reduced fit and miscalibration.

The results suggest that in settings where the observed model miscalibration may be adjusted for with subgroup-specific recalibration or via threshold-adjustment, no approach to learning an ASCVD risk estimator confers more net benefit for each subgroup than unpenalized ERM applied to the entire population. This claim follows from the observation that no alternative approach resulted in greater calibrated net benefit for any subgroup. We find that the net benefit for each population is maximized for each subgroup at a threshold on the risk score that is consistent with the analysis presented in section 2.2.

In cases where we observe improvements in the unadjusted net benefit over ERM, or little to no change despite a reduction in AUC, the differences directly follow from improvements in the calibration of the model derived from the alternative approach. We observe such effects for models trained with objectives that penalize equalized odds to a minor degree, those trained with stratified ERM procedures that train a separate model for each subgroup, as well as for regularized fairness objectives and DRO procedures that operate over the AUC assessed for each subgroup. Taken together, these results indicate that models derived from unpenalized ERM should not necessarily be assumed to be well-calibrated in practice, further highlighting the importance of model development, selection, and post-processing strategies that aims to identify the best-fitting, well-calibrated model for each subgroup.

While this work motivates the use of approaches that reason about algorithmic fairness in terms of the interplay of threshold selection, calibration, and net benefit, such assessments are not comprehensive and rely on assumptions that warrant further examination. First, the analysis relies on a notion of optimal decision-making given a score output by a predictive model, which differs from reasoning about decision-making on the basis of the optimal score that outputs the conditional expectation of the outcome given the covariates. As a result, calibration-based assessments do not account for unrealized net benefit that could be attained if a model were to better fit the data, and thus can be misleading as a notion of fairness when the model is well-calibrated but poorly predicts the outcome for some subgroups [24, 25].
The analysis presented in section 2.2 uses the assumption of invariance across subgroups of the utility of decision-making conditioned on the risk of the outcome to motivate the use of single decision threshold for all subgroups. While this assumption is strong, it is plausible that the analysis could be extended to account for the preferences of subgroups or individual patients. Furthermore, in cases where threshold selection is constrained, such as when a predictive model is used for referral to a clinical service that cannot process more than a fixed number of cases due to resource constraints [15, 47], then it may not be practical to operate at the desired thresholds. In that case, differences in the magnitude of the unrealized benefit across subgroups are likely if the distribution of risk differs across subgroups, even if sufficiency holds and thresholds are selected in a preference-concordant manner for each subgroup.

The presence of measurement error in outcomes that differs systematically across subgroups poses a major challenge for algorithmic fairness assessments [60]. The analysis of Obermeyer et al. [64] demonstrated that this form of measurement error can mask consequential violation of sufficiency with respect to the ideal unobserved outcome not subject to measurement error. The presence of such measurement error could result in differences in measured outcome incidence across groups that imply violation of equalized odds, demographic parity, or predictive parity with respect to the measured outcome. However, consistent with the recommendation of Obermeyer et al. [64], we argue for endeavoring to understand the mechanism of the measurement error to conduct a fairness assessment with respect to a proxy of the unobserved outcome that plausibly does not contain differential measurement error across subgroups.

Finally, it is important to recognize that the algorithmic fairness paradigm, inclusive of the approach considered in this work, is insufficient to characterize the extent to which machine learning systems may exacerbate health disparities or promote health equity [12, 18, 31, 36, 59, 71, 89]. The reasons for this are several-fold, but primary among them is the observation that algorithmic fairness techniques broadly do not consider the mechanisms through which health disparities arise as a result of structural racism and economic inequality, nor how potential interventions may counteract those mechanisms to promote health equity [5, 6, 50, 65]. Furthermore, the narrow scope of statistical algorithmic fairness assessments does not, by default, consider the context, values, and norms underpinning problem formulation, data collection, and measurement, nor the benefits and harms of the downstream model-guided intervention [60, 68]. However, in considering the effect of the properties of the decision-making context on best practices for algorithmic fairness assessments and model development, this work takes a small step towards incorporating aspects of this broader context into the algorithmic fairness paradigm.
