ABSTRACT

We report the discovery of K2-31b, the first confirmed transiting hot Jupiter detected by the K2 space mission. We combined K2 photometry with FastCam lucky imaging and FIES and HARPS high-resolution spectroscopy to confirm the planetary nature of the transiting object and derived the system parameters. K2-31b is a 1.8-Jupiter-mass planet on a 1.26-day orbit around a G7V star (M
total = 0.91 M⊙, R
total = 0.78 R⊙). The planetary radius is poorly constrained (0.7 < R_p < 1.4 R_Jup) owing to the grazing transit and the low sampling rate of the K2 photometry.

Key words: planets and satellites: detection – planets and satellites: individual (EPIC, 204129699, b) – stars: fundamental parameters

1. INTRODUCTION

The advent of space-based transit surveys such as CoRoT (Baglin et al. 2002) and Kepler (Borucki et al. 2010) has provided a major breakthrough for exoplanetary science, in terms of both the number of discoveries and the precision of measured exoplanet radii. Unfortunately, the second reaction wheel of the Kepler spacecraft failed in 2013 May affecting the pointing precision of the telescope. The mission—now called K2—was resumed in 2014 by adopting a different observing strategy that uses only two reaction wheels and thrusters to control the pointing of the telescope (Howell et al. 2014). The capability of K2 to detect small transiting planets in short-period orbits around relatively bright stars has recently been shown (e.g., Vanderburg et al. 2015).

Although much interest is focused on finding Earth-size planets because they are central to astrobiology, hot Jupiters still remain important targets for investigating migration mechanisms and star–planet tidal interactions. Only 21 hot Jupiters (>0.3 M_Jup) on planetary orbits smaller than 1.3 days are confirmed to date (2016 August; see exoplanet.eu).

We report here the discovery of K2-31b, a short-period giant planet transiting a V = 10.8 mag star observed by the K2 mission. We combined the K2 photometry with ground-based follow-up observations to confirm the system and derive its fundamental parameters. We have also shown that grazing transits can entail a correlation between the relative stellar radius R_*/R_p and the orbital inclination i17 when estimating the system parameters. This paper is the collaborative work of two teams dedicated to the detection, analysis, and follow-up of K2 targets, namely, the Kepler Exoplanet Science Team and the ESPRINT team (Sanchis-Ojeda et al. 2015).

2. K2 PHOTOMETRY

The star K2-31 (Table 1) was observed in the long cadence mode (T_expo ~ 29 minutes) by K2 for about 80 consecutive days as part of Campaign 2 (2014 August 23–November 13). In contrast to the original Kepler mission, K2 provides only target pixel files and not “ready-to-use” detrended light curves. The target pixel files contain images with the calibrated flux, the subtracted background, and the removed cosmic rays. The light curve was automatically extracted by using a software developed by the Rhenish Institut for Environmental Research, department of planetary research (RIU-PF). The software detects the target stars in the pixel files, calculates the stellar masks, compensates the translation of the targets on the CCD.

17 In this work, the orbital inclination describes the angle between the normal vector perpendicular to the orbital plane of the planet and the line of sight from the observer point of view. The smallest inclination of ~90° means an edge-on observation of the transiting planet in front of the star.
by shifting the masks, integrates the flux within the stellar masks, and creates a light curve by listing the integrated flux from each pixel file as a function of time (Figure 1, upper panel). Flux variations caused by the rotational drift of the spacecraft and the periodic pointing corrections of the thrusters are corrected using a technique similar to those used by Vanderburg & Johnson (2014) and Lund et al. (2015).

The K2 light curves of Campaign 2 were independently processed and searched for planetary transits by two teams within our collaboration, namely, the DLR in Berlin and the RIU-PF in Cologne, using two different software packages (DST, Cabrera et al. 2012; EXOTRANS, Grziwa et al. 2012). Prior to the transit search, the Cologne team filtered the light curves using the wavelet based filter VARLET and PHALET (Grziwa & Pätzold 2016) to reduce stellar variabilities and instrument systematics (Figure 1, lower panel).

A transit-like signal with a depth of 0.6 % occurring every ~1.26 days was detected by both teams in the light curve of K2-31 (Figure 2). Since the transit is V-shaped, it was suspected that it might be caused by an eclipsing binary whose light contaminates the mask of the target star. The candidate was not discarded though, because grazing transiting planets also exhibit V-shaped signals. Since the star is relatively bright and the first reconnaissance observations can be carried out quickly, the candidate was included in the list for follow-up observations. The confirmation of the planetary nature of this candidate came very promptly as described in Section 3.

The unfiltered light curve of K2-31 also shows quasi-periodic flux variations with a peak-to-peak amplitude of ~1% (Figure 1). The flux variability is very likely caused by magnetic active regions moving in and out of sight as the star rotates. The stellar rotation period was inferred to be $P_{\text{rot}} = 18.38 \pm 0.06$ days using the autocorrelation method described in McQuillan et al. (2014).

3. GROUND-BASED FOLLOW-UP OBSERVATIONS

Follow-up observations were performed in order to exclude the false positive scenario (Brown 2003) and to derive the mass of the planet. High-resolution imaging of K2-31 was obtained on 2015 April 15 using the FastCam lucky imaging camera at the 1.5 m Carlos Sanchez Telescope in Tenerife. Ten data cubes of 1000 images were taken, each with an exposure time of 50 ms. The data were reduced following Jódar et al. (2013). The frames were shifted and co-added to produce a final, high-SNR, high-resolution image. K2-31 appears to be an isolated object. Potential visible companions with $3 \lesssim \Delta \text{mag} \lesssim 6$ can be excluded up to 3° from the target star. Companions with $\Delta \text{mag} \lesssim 3$ can be discarded as close as 0.5°.

The radial velocity (RV) follow-up of K2-31 started in 2015 May with the FIES spectrograph (Telting et al. 2014) mounted at the 2.56 m Nordic Optical Telescope (NOT) of Roque de los Muchachos Observatory (La Palma, Spain). Six high-resolution spectra ($R = 67,000$) at an exposure time of 15–20 minutes were acquired, which resulted in an SNR of 30–38 pixel$^{-1}$ at 5500 Å in the extracted spectra. The RV drift of the instrument was traced by taking long-exposure ($T_{\text{exp}} \approx 30$ s) ThAr spectra right before and after each observation following the observing strategy described by Gandolfi et al. (2015). The data were reduced using standard procedures and RV measurements and were extracted via multi-order cross-correlation with the RV standard star HD 182572, which was observed with the same instrument set-up as the target object.

Three additional spectra were collected in 2015 June with the HARPS spectrograph (Mayor et al. 2003) mounted at the 3.6 m ESO telescope (La Silla, Chile) as part of the ESO program.

**Figure 1.** Upper panel: K2-31’s light curve extracted from the target pixel files. Lower panel: light curve filtered with VARLET and PHALET.

**Figure 2.** Upper panel: phase-folded transit light curve of K2-31b and an exemplary best-fitting transit model (red). Lower panel: residuals to the transit fit.
095.C-0718(A). The exposure time was 20 minutes resulting in an SNR of 36–56 pixel$^{-1}$ at 5500 Å in the extracted spectra. Radial velocities were obtained by multi-order cross-correlation with a numerical mask using the HARPS pipeline.

The FIES and HARPS RV measurements are listed in Table 2, along with the error bars, barycentric Julian dates in barycentric dynamical time, and the cross-correlation function (CCF) bisector spans. The two sets of RV measurements were fit to a Keplerian model, as described in Section 5. Figure 3 shows the RV measurements—after subtracting the RV offset between the two instruments and the systemic velocity—phase-folded to the orbital period (upper panel), along with the RV residuals (lower panel). No significant correlation between the CCF bisector spans and the RVs was found indicating that the Doppler shifts observed in K2-31 are induced by the orbital motion of the planet rather than stellar activity or a blended eclipsing binary.

4. FUNDAMENTAL PARAMETERS OF THE HOST STAR

Two independent analyses were performed to estimate the spectroscopic parameters of K2-31 from the co-added FIES and HARPS spectra. The first method fits the observed spectra to a grid of theoretical models from Castelli & Kurucz (2004), Coelho et al. (2005), and Gustafsson et al. (2008), using spectral features that are sensitive to different parameters. The calibration equations for Sun-like stars from Bruntt et al. (2010) and Doyle et al. (2014) were adopted to determine the microturbulent $v_{\text{micro}}$ and macroturbulent $v_{\text{macro}}$ velocities, respectively. The projected stellar rotational velocity $v \sin i = 2.5 \pm 0.5$ km s$^{-1}$ was measured by fitting the profile of several clean and unblended metal lines. The second method relies on the use of the spectral analysis package Spectroscopy Made Easy (SME; version 4.43 Valenti & Piskunov 1996; Valenti & Fischer 2005). SME calculates, for a set of given stellar parameters, synthetic spectra of stars are used to fit and observed high-resolution spectra using a $\chi^2$ minimization procedure. These two analyses provided consistent results well within the error bars, regardless of the method and spectrum used. The final adopted values are listed in Table 1. A effective stellar temperature $T_{\text{eff}} = 5280 \pm 70$ K, a surface gravity log $g = 4.60 \pm 0.07$, and a metallicity [Fe/H] = 0.08 $\pm$ 0.05 was calculated. Using the Straizys & Kuriliene (1981) calibration scale for dwarf stars, the effective temperature of K2-31 defines the spectral type of the host star as G7 V. A stellar mass of $0.91 \pm 0.06 M_\odot$ and a stellar radius of $0.78 \pm 0.07 R_\odot$ were determined using the empirical calibrations from Torres et al. (2010). Also Dai et al. (2016) Doppler monitored K2-31. They calculated slightly higher values for temperature ($T_{\text{eff}} = 5412 \pm 34$ K), log $g$ (4.44 $\pm$ 0.05), and also higher values for metallicity (0.20 $\pm$ 0.05). This results in a slightly different star model with a higher mass (1.000 $\pm$ 0.064 $M_\odot$) compared to our values but is consistent inside the error bars. They also calculated a higher stellar radius (0.986 $\pm$ 0.070 $R_\odot$) compared to our values (0.78 $\pm$ 0.07 $R_\odot$).

5. DATA MODELING

By analyzing our FIES and HARPS measurements, as described in Section 3, we calculated a planetary mass of 1.774 $\pm$ 0.079 $M_{\text{Jup}}$ for K2-31b. In Dai et al. (2016), a planetary mass of 1.856 $\pm$ 0.084 $M_{\text{Jup}}$ was calculated using their own PFS and TRES RV data. They also combined their PFS and TRES measurements with our FIES and HARPS data, getting nearly the same results with a slightly smaller error (1.857 $\pm$ 0.081 $M_{\text{Jup}}$). Nevertheless, all three mass determinations are consistent inside the error bars and reveal the planetary nature of this hot Jupiter.

Unfortunately, retrieving the system parameters from light-curve analysis was more problematic. The grazing transit of K2-31b implies that the light-curve modeling alone cannot provide a unique best-fitting solution (Csizmadia et al. 2013; Müller et al. 2013). A correlation exists between the planet-radius ratio $R_p/R_s$, the impact parameter $b$ (or inclination), and the semimajor-axis ratio $a_p/R_s$. Constraints are thus needed to reduce the degeneracy of the parameter space. The impact parameter must be $b \gtrsim 0.9$ following Csizmadia et al. (2015). The estimate of the lower limit for the impact parameter uses the length of the transit and the estimated stellar mass and radius. The orbital period, the spectroscopically derived stellar mass and radius, and $Kepler$’s third law, constrain the scaled semimajor axis to $a_p/R_s = 6.05 \pm 0.50$, assuming a circular orbit.\footnote{Although the RVs are better fitted by a 0.012 eccentricity, there is an \(~60\)% probability that the best-fitting eccentric solution arises by chance if the orbit is actually circular (Lucy & Sweeney 1971).}

![Figure 3](image-url)

Figure 3. Upper panel: phase-folded FIES (green points) and HARPS (red points) RVs of K2-31 and Keplerian fit to the data. Lower panel: radial velocity residuals.
transit model by Mandel & Agol (2002), EXOFAST (Eastman et al. 2013) and PyTransit (Parviainen 2015) were used to perform a simultaneous fit to the RV and K2 data and to obtain an estimate of the model posterior distribution using Markov chain Monte Carlo simulations. The Transit Light Curve Modeling (TLCM) code (Csizmadia et al. 2015), Transit Analysis Package (TAP; Gazak et al. 2012) and UTM/UFIT (Deeg 2014) were used to model the K2 data only.

EXOFAST, PyTransit, and TAP account for the K2 low-acquisition rate by calculating the transit model for 8–10 subsamples per long cadence data point. In the case of TLCM, the transit model was calculated for 33 equidistantly distributed points inside a long cadence measurement and then integrated using a Simpson-integrator. All five software packages showed the same result, which is listed in Table 3. The correlation between the impact parameter and the radius ratio cannot be resolved, though as many parameters as possible were constrained.

Figure 4 shows the unresolved correlation between inclination $i$ and relative radius $R_p/R_e$. Assuming that planetary systems are randomly oriented, their inclination distribution follows a probability density proportional to $\sin i$, which can be assumed to be uniform in the inclination range of $80^\circ$–$79.1^\circ$ that corresponds to the planet’s orbital inclination. Given the absence of any further indicator that prefers some planet-size anywhere within the range of 0.7–1.4 $R_{\text{Jup}}$, we consider that the planet has a radius within that range with a uniform distribution of probability. Indications of the same problem were reported for Kepler-447b (Lillo-Box et al. 2015), who decided to increase the error bar of the planetary radius.

We can determine the effective temperature of the planet using the host star’s parameters and considering that the planet is tidally locked. Assuming a low albedo and that the stellar flux energy is distributed over the star-facing hemisphere results in an equilibrium temperature of the planet of 1750 K. In the Kepler bandpass, reflected light is therefore expected to dominate thermal emission from the planet when observed near secondary eclipse. A search for such eclipses did not lead to any reliable detection. We found an amplitude upper limit of 76 ppm, which implies an upper limit to the planet-to-star surface-brightness ratio of 0.01, corresponding to a planetary geometric albedo of less than 0.4. The planet is therefore rather dark, as are most hot Jupiters (Cowan & Agol 2011). We note that this albedo-limit is not affected by the uncertainties in the planet’s size.

6. SUMMARY AND FINAL REMARKS

K2-31b is the first hot Jupiter detected and confirmed by the K2 mission. K2-31 is a relatively bright ($V = 10.8$ mag) G7 V star of $M_* = 0.91 \pm 0.06 M_{\odot}$ and $R_* = 0.78 \pm 0.07 R_{\odot}$, hosting a short-period ($P_{\text{orb}} = 1.26$ days) Jupiter-like planet with a mass of 1.8 $M_{\text{Jup}}$. Dai et al. (2016) published additional RV measurements of K2-31. Their results of the stellar and planetary mass are consistent with our results. Their values for the stellar radius are slightly higher than our values. This would also change the absolute planetary radius, but the error is dominated by the uncertainty of the relative planetary radius. The radius of the planet could only be determined in the range of 0.7–1.4 $R_{\text{Jup}}$ because of the grazing transit combined with the K2 low-acquisition rate. The detection of correlations between different parameters is not guaranteed when using MCMC simulations. The use of Monte Carlo simulations would suggest more precise results for the planetary radius with error bars that are unrealistically small. The estimates of the planetary radius and orbital parameters could be improved with additional optical and near-infrared transit observations, as recently shown by Mancini et al. (2014) for the grazing transit of WASP-67.

Blended eclipsing binary systems whose light is diluted by the main target inside the photometric mask often cause V-shaped transits that are difficult to distinguish from rare grazing planetary transits (Brown 2003). It is possible that some V-shaped transits are discarded because they are misidentified as background binaries. In the case of K2-31, the V-shaped transit is caused by a grazing hot Jupiter. Oshagh et al. (2015) stated that the number of known grazing transiting exoplanets are lower than what we expect. This new detection is important to understand the detection biases. Follow-up observations are needed in order to assess the true nature of V-shaped transit signals in the absence of higher time-sampling and/or multi-color transit photometry. The short orbital period (1.26 days) and transit duration (~1 hr) are a definitive

### Table 3: Orbital and Planetary Parameters

| Parameter                        | Value                        |
|----------------------------------|------------------------------|
| Period (day)                     | 1.257850 ± 0.000002          |
| Mid-transit epoch (BJD-2454833 day) | 2358.70889 ± 0.00024        |
| Transit duration (day)           | 0.0409 ± 0.0002              |
| Linear limb darkening coefficient | 0.514 ± 0.169               |
| Quadratic limb darkening coefficient | 0.296 ± 0.126             |
| Scale semimajor axis $a_p/R_e$   | 6.05 ± 0.50                 |
| Impact parameter $b$             | 0.9–1.05                    |
| Orbit inclination (deg)          | 80.7 – 79.1                 |
| Eccentricity                     | 0 (fixed)                   |
| Planet-to-star radius ratio $R_p/R_e$ | 0.09–0.18           |
| RV semi-amplitude variation (km s$^{-1}$) | 0.3509 ± 0.0010        |
| Systemic velocity (FIES) (km s$^{-1}$) | −4.9434 ± 0.0026        |
| Systemic velocity (HARPS)(km s$^{-1}$) | −4.7511 ± 0.0011        |
| Semimajor axis (au)              | 0.0220 ± 0.0018             |
| Planet mass $M_p$ [$M_{\text{Jup}}$] | 1.774 ± 0.079             |
| Planet radius $R_p$ [$R_{\text{Jup}}$] | 0.71–1.41              |
advantage for the observation schedule and only a small number of short-period hot Jupiters are detected to date.

Based on observations made with the Nordic Optical Telescope (NOT) operated on the island of La Palma by Nordic Optical Telescope Scientific Association in the Observatorio del Roque de Los Muchachos and with the Telescopio Carlos Sanchez (TCS) at Teide Observatory on Tenerife, both of the Instituto de Astrofísica de Canarias. H.D. and D.N. acknowledge support by grant AYA2012-39346-C02-02 of the Spanish Secretary of State for R&D&i (MINECO). This paper includes data collected by the Kepler-K2 mission. Funding for the Kepler mission is provided by the NASA Science Mission directorate. We would like to thank the anonymous referee for valuable comments, which improved the paper.

Facilities: Kepler (K2), NOT (FIES), ESO:3.6 m (HARPS), Sanchez (FAST-CAM).

Software: DST, EXOTRANS, SME, TAP, EXOFAST, TLCM, PyTransit, UTM/UFIT.
