ABSTRACT: We present results of a computation of NLO QCD corrections to the production of an off-shell top–antitop pair in association with an off-shell $W^+$ boson in proton–proton collisions. As the calculation is based on the full matrix elements for the process $pp \rightarrow e^+\nu_e\mu^-\nu_\mu\tau^+\nu_\tau\bar{b}\bar{b}$, all off-shell, spin-correlation, and interference effects are included. The NLO QCD corrections are about 20% for the integrated cross-section. Using a dynamical scale, the corrections to most distributions are at the same level, while some distributions show much larger $K$-factors in suppressed regions of phase space. We have performed a second calculation based on a double-pole approximation. While the corresponding results agree with the full calculation within few per cent for integrated cross-sections, the discrepancy can reach 10% and more in regions of phase space that are not dominated by top–antitop production. As a consequence, on-shell calculations should only be trusted to this level of accuracy.

KEYWORDS: Standard Model, top quark, NLO QCD, off-shell, LHC
1 Introduction

The production of top–antitop-quark pairs in association with a massive electroweak vector boson is of great importance at the Large Hadron Collider (LHC), both as a test of the Standard Model (SM) and for the search for effects of new physics. The presence of a dominant resonance structure that features three massive unstable particles makes such a process one of the heaviest signatures that can be detected and investigated at the LHC.

Both \( t\bar{t}W^\pm \) and \( t\bar{t}Z \) production have been observed and studied by the ATLAS and CMS experiments with 8 TeV [1, 2] and 13 TeV centre-of-mass (CM) energy data [3–6]. In particular, the ATLAS collaboration has measured \( t\bar{t}W^\pm \) production in the three-charged-leptons channel [5], which is the process considered in this paper. The collected data of the LHC Runs 1 and 2 and the luminosities expected in the coming runs will deliver an improved understanding of the dynamics of \( t\bar{t}V \) processes.

The study of \( t\bar{t}V \) production is expected to provide a direct access to the top-quark coupling to gauge bosons, and specifically to possible deviations from the SM prediction due to new physics [7–9]. The \( t\bar{t}W^\pm \) and \( t\bar{t}Z \) signatures can be directly affected by beyond-Standard Model (BSM) effects, for example by the presence of supersymmetry [10, 11], vector-like quarks [12], little Higgs bosons [13] and technicolour [14]. The SM \( t\bar{t}Z \) production, with \( Z \rightarrow \nu\bar{\nu} \), represents an important background for dark-matter signals [15].
In particular, the associated production of top quarks with a $W^\pm$ boson in the fully-leptonic decay channel represents a rare process at the LHC, owing to the presence of two like-sign leptons in the final state. Therefore, despite a relatively low rate, it constitutes an optimal signature for BSM searches, with a particular focus on supersymmetry [10, 11], supergravity [16], Majorana neutrinos [17] and modified Higgs sectors [18, 19]. The $t\bar{t}W^\pm$ signature could noticeably improve the investigation of the $t\bar{t}$ charge asymmetry [20], that is expected to be larger than in pure $t\bar{t}$ production, due to the absence of neutral initial states at leading order (LO) and next-to-leading order (NLO). Moreover, the study of polarisation-related observables in $t\bar{t}W^\pm$ production provides additional sensitivity to BSM effects [20].

The $t\bar{t}W$ production is also an important background for top–antitop production in association with a Higgs boson [21], which has been recently observed [22, 23] and further investigated in the multi-lepton channel [24, 25] at the LHC.

Both in the direct measurement of $t\bar{t}W^\pm$ production [4, 5] and in the measurement of the $t\bar{t}H$ signal [24, 25], a tension between 13 TeV CM data and the SM predictions has been observed in the $t\bar{t}W^\pm$ modelling, both in the inclusive cross-section, and in kinematic regimes where $t\bar{t}W^\pm$ production is expected to be the leading contribution. In order to address such a tension with the data and to allow for more precise investigations, improved precision and accuracy are needed for the theoretical description of this process.

A number of phenomenological studies are already present in the literature. The hadronic production of $t\bar{t}W^\pm$ was first computed with NLO QCD accuracy for LHC energies including top-quark decays with full spin correlations, using decay chains to simulate the semileptonic final state [26]. Parton-shower effects of both $t\bar{t}W^\pm$ and $t\bar{t}Z$ production with semileptonic top decays were added on top of NLO QCD predictions for the two- ($W$) and three-charged-leptons ($Z$) final states at the LHC at 7/8 TeV CM energy [27]. The importance of this processes for the study of the $t\bar{t}$ charge asymmetry [20] and its impact on $t\bar{t}H$ searches [21] was examined at NLO QCD in inclusive production. The impact of electroweak corrections on $t\bar{t}W^\pm$ production was investigated in inclusive production (no decays of the three resonances) in Refs. [28, 29]. Resummed calculations for the on-shell production of $t\bar{t}$ in association with a heavy boson were performed up to next-to-next-to-leading-logarithmic (NNLL) accuracy [30–34]. An NLO QCD analysis including parton-shower matching with the focus of effects of spin correlations and subleading electroweak corrections on asymmetries was presented in Ref. [35]. The first computation of NLO QCD corrections including all off-shell effects and spin correlations appeared very recently [36] for hadronic collisions at 13 TeV CM energy in the three-charged-leptons decay channel.

The goal of this paper is to present an independent computation of the complete NLO QCD corrections to the off-shell production of $t\bar{t}W^+$ in the three-charged-leptons decay channel. The specific final state we consider, the scale choices we analyse, and the SM input parameters differ from those of Ref. [36]. However, we have reproduced the results of Ref. [36] using the same setup employed therein, finding very good agreement both at the integrated and at the differential level.

This work is organised as follows. In Section 2 we present details of our calculation of the $t\bar{t}W^+$ process, including a description of real and virtual NLO corrections. We describe
an approximated calculation of the same process that relies on double-pole-approximation techniques and a number of numerical checks we have performed to validate the full off-shell computation. In Section 3 we present the results of numerical simulations both at the integrated and at the differential level. After introducing the setup for the numerical simulations in Section 3.1, we discuss the scale choice in Sections 3.2 and 3.3.1. In Section 3.3.2 we analyse a number of kinematic variables, including both directly measurable observables at the LHC and kinematic variables based on Monte Carlo truth. The results obtained from full matrix elements are compared with those in the double-pole approximation in Section 3.4. We draw our conclusions in Section 4.

2 Details of the calculation

In this paper we present the NLO QCD corrections to the process

\[ pp \rightarrow e^+ \nu_e \mu^- \bar{\nu}_\mu \tau^+ \nu_\tau b \bar{b}. \]  

(2.1)

The calculation has been performed with MoCaNLO, a Monte Carlo generator that has been used to simulate other processes involving top quarks with NLO EW and QCD accuracy [37–40]. It is interfaced with RECOLA [41, 42] which provides the tree-level and one-loop SM amplitudes using the Collier library [43] to perform the reduction and numerical evaluation of one-loop integrals [44–46].

The leading tree-level contributions to the considered process are of order \( \mathcal{O}(\alpha_s^2 \alpha^6) \), and come uniquely from quark-induced partonic channels. Since we assume a diagonal quark-mixing matrix, the only possible initial states are ud and cs. Similarly to \( t\bar{t} \) production, other LO contributions are either suppressed [\( \mathcal{O}(\alpha^8) \)] or vanishing thanks to colour algebra [\( \mathcal{O}(\alpha_s \alpha^7) \)] and are neglected here. No photon- or gluon-initiated processes contribute to this process at LO.

In the following we focus on the NLO QCD corrections to the leading tree-level contribution, leaving NLO EW corrections to future work. All resonant and non-resonant diagrams of order \( \mathcal{O}(g^2 \alpha^6) \) (Born, tree-level), \( \mathcal{O}(g^3 \alpha^6) \) (real, tree-level) and \( \mathcal{O}(g^4 \alpha^6) \) (virtual, one-loop) are included in the calculation, in order to account for all interferences and off-shell effects related to the electroweak gauge bosons and top quarks.

At Born level, 286 diagrams contribute to each partonic process. The large number of final-state particles allows for several resonance structures, In Fig. 1 we show a few sample diagrams that contribute at LO and feature two, one, or zero resonant top/antitop quarks.

In most of the diagrams, the propagating gluon is radiated from initial-state quarks and converts to b\( \bar{b} \) [see for example Figs. 1(c), 1(d) and 1(f)]. However such diagrams give a small contribution to the squared amplitude, since they do not contain resonant top or antitop quarks. The leading contributions are provided by diagrams with a resonant \( t\bar{t} \) pair, like the one depicted in Fig. 1(a). Also single-top-resonant diagrams like the one in Fig. 1(b) yield a visible contribution at LO. Other diagram topologies give minor contributions: a \( W^+W^- \) pair can be produced via the decay of a Higgs [Fig. 1(c)] or a Z boson [Fig. 1(d)]. We observe that all diagrams contain at least one resonant \( W^+ \) boson.
Given the LO structure of the process, six possible partonic channels contribute to the real corrections at order $\mathcal{O}(\alpha_s^3\alpha_s^6)$,

$$
u_{\nu_e} e^+ \mu^- \bar{\nu}_\mu \tau^+ \nu_\tau b \bar{b} g \quad \text{ug/cg} \rightarrow e^+ \nu_e \mu^- \bar{\nu}_\mu \tau^+ \nu_\tau b \bar{b} d/s$$

$$
\nu_{\nu_e} e^+ \mu^- \bar{\nu}_\mu \tau^+ \nu_\tau b \bar{b} \bar{u}/\bar{c}
$$

Since we consider a final state with three charged leptons, the additional gluon can only be radiated off the initial-state quark lines, the final-state b jets, or internal light-quark, bottom and top-quark propagators. For each real-radiation channel there are 1916 Feynman diagrams contribute. The $q\bar{q}$ channel is the one featuring the largest number of infrared (IR) singular regions, and thus is the most demanding in the numerical calculation. We treat bottom quarks as massless particles and work in the five-flavour scheme. For the final states of the processes (2.2), no initial states involving bottom quarks contribute for a diagonal quark-mixing matrix that we assume.

We treat the IR singularities with the Catani–Seymour subtraction scheme [47]. The initial-state collinear QCD singularities are absorbed in the PDFs via the $\overline{\text{MS}}$ scheme. The spin-correlated and colour-correlated matrix elements entering the unintegrated subtraction counterterms are computed with RECOLA [41, 42]. As a validation of the correct computation of the subtracted real and integrated counterterms, we have varied the $\alpha_{\text{dipole}}$ parameters [48] in the definition of the dipoles, as is further explained in Section 2.4.

Although computing the virtual contributions involves the evaluation of complicated one-loop diagrams (see the following section), the numerical simulation of the (subtracted) real contributions to NLO observables represents the most CPU-intensive part of the calculation, in spite of its tree-level nature and the relatively small number of QCD subtraction...
dipoles. This is due to the large multiplicity of the final state (three coloured partons, six lepton but also due to the relatively small numerical contribution of the virtual corrections. Tackling the NLO EW corrections for the same process will be even more challenging, as the number of QED dipoles is larger than the one of QCD dipoles.

2.2 Virtual corrections

The virtual QCD corrections are obtained by inserting a gluon in the tree-level amplitudes, resulting in roughly 6000 Feynman diagrams for each partonic channel. The most complicated one-loop contributions involve 7-point functions appearing when a virtual gluon connects the initial-state light quarks and a final-state b quark in diagrams which do not feature the $t\bar{t}$ resonance structure. An example is depicted in Fig. 2. The virtual corrections to the considered process are computed with SM amplitudes provided by RECOLA [41, 42] interfaced to the COLLIER library [43] for the numerical evaluation of scalar and tensor one-loop integrals. All unstable particles are treated in the complex-mass scheme [49–52], resulting in complex input values for the electroweak boson masses, the top-quark mass, and the electroweak mixing angle,

$$\mu^2_V = M^2_V - i\Gamma_V M_V \quad (V = W, Z), \quad \mu_1^2 = m_t^2 - i\Gamma_t m_t, \quad \cos^2\theta_w = \frac{\mu_2^2}{\mu_Z^2}.$$  

(2.3)

2.3 Double-pole approximation

The hadronic process defined in Eq. (2.1) is dominated by the resonant production of a top–antitop-quark pair in association with a W$^+$ boson. Most of the results that are present in the literature [20, 21, 28, 29, 31–34] are inclusive, i.e. they rely on the on-shell production of the three massive particles. More refined techniques have been investigated to complement the inclusive results with spin correlations and off-shell effects, without computing the full off-shell process, e.g. using the narrow-width approximation [35, 36]. Such approximations help in assessing the importance of resonance structures as well as in validating parts of the full calculation.

A universal technique for processes dominated by a pair of resonances is the so-called double-pole approximation (DPA), which has been widely used in the literature for the calculation of NLO EW virtual corrections to several processes, like di-boson [50, 53–57], vector-boson scattering [58] and top–antitop pair production [38]. In general, the pole approximation [59, 60] amounts to selecting all diagrams containing the resonance structure.
that is expected to be dominant in the full process. The Breit–Wigner modulation of the selected resonances is preserved with off-shell kinematics, while in the rest of the amplitude the resonant particles are treated with on-shell kinematics, obtained by means of properly defined projections. While the DPA is applied to the virtual contributions, the Born and real contributions to the NLO calculation are usually computed with full matrix elements \[50\]. The extension of this technique to QCD corrections is straightforward.

We have applied a DPA to the top and antitop resonances in order to mimic as much as possible the on-shell calculations that are available in the literature for \( t\bar{t}W \) production. The QCD corrections affect top quarks, being coloured particles, both in the production and in the decay parts of the amplitude. Therefore, both factorisable and non-factorisable gluonic corrections contribute to the resonant production of a \( t\bar{t} \) pair. The factorisable corrections can be written in the general form

\[
\mathcal{M}_{\text{virt, fact}}^{I \rightarrow F_a F_b} = \sum_{h_a, h_b} \mathcal{M}_{\text{LO}}^{I \rightarrow a F_a} \mathcal{M}_{\text{LO}}^{b \rightarrow F_b} + \mathcal{M}_{\text{virt}}^{I \rightarrow a b} \mathcal{M}_{\text{LO}}^{b \rightarrow F_b} + \mathcal{M}_{\text{virt}}^{I \rightarrow a b} \mathcal{M}_{\text{LO}}^{a \rightarrow F_a} \mathcal{M}_{\text{virt}}^{b \rightarrow F_b},
\]

where \( s_a, s_b \) and \( h_a, h_b \) stand for the virtualities and helicities of the intermediate top and antitop quarks, respectively. Further, \( \mathcal{M}_{\text{LO}}^{I \rightarrow a b}, \mathcal{M}_{\text{LO}}^{a \rightarrow F_a}, \mathcal{M}_{\text{LO}}^{b \rightarrow F_b} \) are the \( t\bar{t} \) production amplitude and the top- and antitop-quark decay amplitudes. The non-factorisable corrections to the resonant amplitude have a universal structure \[53, 61, 62\],

\[
2 \text{Re} (\mathcal{M}_{\text{LO}}^* \mathcal{M}_{\text{virt, nfact}}) = |\mathcal{M}_{\text{LO}}|^2 \delta_{\text{nfact}},
\]

and are needed for the complete subtraction of IR singularities, since the real contributions are not treated with the pole approximation \[53\]. Sample diagrams for factorisable and non-factorisable QCD corrections are shown in Fig. 3. The on-shell kinematics for the resonant contributions is obtained by suitable projections of the momenta, which involve some ambiguity. We employ on-shell projections for top quarks that preserve the off-shellness of the corresponding W bosons, in the same fashion as in Ref. \[63\].

In \( t\bar{t}W^+ \) production two virtual \( W^+ \) bosons appear, one of which results from the top-quark decay. Thus, the DPA receives two distinct contributions, one where the top quark decays into \( e^+ \nu_e b \) and one where it decays into \( \tau^+ \nu_\tau b \). Since the interference of these
contributions is not doubly resonant, the full contributions in DPA are simply obtained upon adding these two contributions.

One last remark concerns the definition of the part of the NLO corrections that is calculated in the DPA. In the original DPA computations [50] and in most computations performed with MoCaNLO [38, 40, 58] the DPA has been applied to the sum of the virtual corrections and the $I$-operator of the integrated Catani–Seymour dipoles, while the $P$- and $K$-operators have been calculated with off-shell kinematics. As this treats large contributions in the subtracted and re-added real corrections differently, when done in combination with a small $\alpha_{\text{dipole}}$ parameter [64] this tends to worsen the agreement with the full computation [65]. This can be improved in different ways. One possibility is to calculate only the $\alpha_{\text{dipole}}$-independent part of the $I$-operators, i.e. the one for $\alpha_{\text{dipole}} = 1$, within the DPA but the $\alpha_{\text{dipole}}$-dependent part, which contains logarithms of $\alpha_{\text{dipole}}$, with full kinematics. This allows to cancel exactly the $\alpha_{\text{dipole}}$-dependence in the sum of integrated and subtraction dipoles. Another option is to apply the DPA only to the virtual corrections with IR singularities subtracted via an appropriate choice of regularisation parameters. Since the virtual corrections are smaller than the contributions of the integrated dipoles, as shown in Section 3.4, this provides actually a better approximation of the calculation with full matrix elements.

### 2.4 Validation

The calculation presented in this paper has been validated at several levels.

The correct functioning of the subtraction of IR singularities has been checked performing the computation with different values of the $\alpha_{\text{dipole}}$ parameters that enter the calculation of integrated and unintegrated subtraction dipoles [48]. Setting $\alpha_{\text{dipole}} < 1$ enables one to restrict the phase-space integration to the singular regions, in order to avoid problems from sizeable remappings of momenta in the Monte Carlo integration. Varying these parameters is equivalent to changing the definition of the subtraction counterterms, but the sum of the subtracted real and integrated dipoles remains independent of the choice of $\alpha_{\text{dipole}}$.

As a validation of the virtual contributions, we have compared the results based on full matrix elements with the corresponding DPA results, including factorisable and non-factorisable QCD corrections (see Section 2.3). The agreement between the two results is astonishingly good. At the integrated level, the discrepancy between the two calculations is of order 0.2%. A more detailed discussion on this comparison is given in Section 3.4.

The specific final state that we consider features three charged leptons with different flavours. However, in order to further check the computations with full matrix elements, we have independently reproduced some results that have been recently published in Ref. [36], where the considered final state involves two identical positrons and a muon. Employing the same final state, SM input parameters, selection cuts ($p_{T,b} > 25$ GeV), PDF set (NNPDF3.0), as well as factorisation and renormalisation scale, we obtain the following

---

1In practice we discard the IR poles and set the parameter $\text{muir}$ of Collier equal to the top-quark mass.
integrated cross-sections:

\[ \sigma_{\text{LO}} = 0.1147(1)^{+0.0304}_{-0.0224} \text{ fb} \quad (\text{Ref. [36]} : 0.1151^{+0.0305}_{-0.0225} \text{ fb}), \]

\[ \sigma_{\text{NLO}} = 0.1247(4)^{+0.0046}_{-0.0078} \text{ fb} \quad (\text{Ref. [36]} : 0.1244^{+0.0043}_{-0.0077} \text{ fb}). \]

The only difference between the two calculations lies in the treatment of resonant electroweak vector bosons, which in Ref. [36] is performed in the fixed-width scheme, while in our calculation the complex-mass scheme is employed (see Section 2.2). The agreement between the two calculations is excellent, both at LO and at NLO QCD. This holds for the central values of the integrated cross-sections and for the theoretical uncertainties given by scale variations.

We have also studied some differential distributions in the setup of Ref. [36], finding good agreement in the absolute distributions and in the shapes of relative corrections. In Fig. 4 we show the LO and NLO distributions in the variable \( H_{\text{vis}}^T \) that is the scalar sum of the transverse momenta of all visible particles (excluding the additional radiated gluon), and for the rapidity–azimuthal-angle distance between the leading positron, \textit{i.e.} the positron with highest transverse momentum, and the muon. From a direct comparison with Figs. 5 and 7 of Ref. [36], we find the same dependence of the \( K \)-factors on the considered variables, as well as very similar scale uncertainty bands in the various kinematic regions. We have computed differential distributions in all of the kinematic variables that are presented in Ref. [36], finding good agreement in all cases.
3 Numerical results

3.1 Input parameters

In the following, we present results for the LHC at a CM energy of 13 TeV. We consider a final state with three charged leptons of different flavours, which are all assumed to be massless, i.e. also $m_\tau = 0$. We note that our results can be used as well for the case of identical leptons in the final state after applying appropriate symmetry factor $1/2$ up to interference effects. These interference effects are not doubly resonant and suppressed by factors $\Gamma_1/m_1$. However, calculating the NLO corrections for identical leptons does not pose any problems for our machinery and has in fact done to compare with as Ref. [36], as described in Section 2.4. We work in the five-flavour scheme and treat all light quarks, including the b quarks, as massless.

The masses and widths of the electroweak bosons are chosen according to Ref. [66]:

\begin{align}
M_W^{\text{OS}} &= 80.379 \text{ GeV}, \\
\Gamma_W^{\text{OS}} &= 2.085 \text{ GeV}, \\
M_Z^{\text{OS}} &= 91.1876 \text{ GeV}, \\
\Gamma_Z^{\text{OS}} &= 2.4952 \text{ GeV}, \\
M_H &= 125.00 \text{ GeV}, \\
\Gamma_H &= 0.00407 \text{ GeV}.
\end{align}

(3.1)

The masses of the vector bosons are converted to their pole values by means of the following relations [67]:

\begin{align}
M_V &= \frac{M_V^{\text{OS}}}{\sqrt{1 + (M_V^{\text{OS}}/\Gamma_V^{\text{OS}})^2}}, \\
\Gamma_V &= \frac{\Gamma_V^{\text{OS}}}{\sqrt{1 + (M_V^{\text{OS}}/\Gamma_V^{\text{OS}})^2}}.
\end{align}

(3.2)

The top-quark mass and widths are fixed as

\begin{align}
m_t &= 173.0 \text{ GeV}, \\
\Gamma_t^{\text{LO}} &= 1.44 \text{ GeV}, \\
\Gamma_t^{\text{NLO}} &= 1.34 \text{ GeV}.
\end{align}

(3.3)

While the top-quark width at LO has been computed based on the formulas of Ref. [68], the width at NLO QCD has been obtained upon applying the relative NLO QCD corrections of Ref. [69] to the LO width. The electroweak coupling is extracted from the Fermi constant $G_\mu$ [50] by means of

\begin{align}
\alpha &= \frac{\sqrt{2}}{\pi} G_\mu M_W^2 \left[1 - \left(\frac{M_W^2}{M_Z^2}\right)^2\right],
\end{align}

(3.4)

where $G_\mu = 0.16638 \cdot 10^{-5} \text{ GeV}^{-2}$.

The masses of unstable particles, i.e. the electroweak vector bosons and the top quark are treated in the complex-mass scheme [49–52] in all parts of the computation. As a consequence, the electroweak mixing angle and the couplings become complex as well.

For the LO (NLO) calculation, we use NNPDF3.1 PDFs [70] computed at LO (NLO) with $\alpha_s = 0.118$. The strong coupling constant $\alpha_s$ used in the calculation of the amplitudes matches the one used in the evolution of PDFs. The PDFs and the running of $\alpha_s$ are obtained by interfacing MoCaNLO with LHAPDF6 [71].

QCD partons with $|\eta| < 5$ are clustered into jets by means of the anti-$k_t$ algorithm [72] with resolution radius $R = 0.4$. 

– 9 –
Our choice of selection cuts reflects those applied by ATLAS in a recent analysis [5] (see Table 5 therein). In particular, we ask for exactly two b jets in the final state, assuming a perfect b-tagging efficiency, which are required to fulfil

\[ p_{T,b} > 25 \mathrm{GeV}, \quad |\eta_b| < 2.5. \]  

(3.5)

We apply basic transverse-momentum, rapidity and isolation cuts to the three charged leptons,

\[ p_{T,\ell} > 27 \mathrm{GeV}, \quad |\eta_\ell| < 2.5, \quad \Delta R_{\ell b} > 0.4. \]  

(3.6)

While these cuts are applied to the light leptons \( \ell = e, \mu \) by ATLAS, we apply them also to \( \tau \) leptons. We remind the reader that our results can be applied as well for final states with identical leptons within a good approximation. No specific veto is imposed on the additional light jet that may come from real radiation at NLO QCD, in case it is not recombined with a b jet. Furthermore, we do not impose any restriction on the missing transverse momentum.

### 3.2 Fiducial cross-sections

A common choice in the literature for the factorisation and renormalisation scale for the considered process is [27, 73]

\[ \mu_0^{(a)} = m_t + \frac{M_W}{2}, \]  

(3.7)

which is adapted to the masses of the leading resonance structure contributing to the final state under investigation. In addition to this fixed scale, we have considered dynamical scales that depend on the transverse momenta of the final-state particles. One choice depends on the \( H_T \) variable, defined as

\[ H_T = p_{T,\text{miss}} + \sum_{i=b,\ell} p_{T,i}, \]

where the sum runs over all b jets and charged leptons, excluding additional light jets that may arise from real radiation at NLO. We have checked that the inclusion of the \( p_T \) of additional radiation would lead to a significant deterioration of the scale dependence of the fiducial cross-section. Since \( H_T \) is measurable at the LHC, it represents a natural scale choice in the computation of the full off-shell process. We have investigated two different variants of scales based on \( H_T \),

\[ \mu_0^{(b)} = \frac{H_T}{2} \quad \text{and} \quad \mu_0^{(c)} = \frac{H_T}{3}, \]  

(3.8)

where the second one has been proposed in Ref. [36].

An alternative definition of a dynamical scale is based on the top and antitop transverse masses, and is motivated by the choice made in Refs. [39, 40] for \( t\bar{t} \) and \( t\bar{t}H \) production at the LHC,

\[ \mu_0^{(d)} = (M_{T,t} M_{T,\bar{t}})^{1/2} = \left( \sqrt{m_t^2 + p_{T,t}^2} \sqrt{m_{\bar{t}}^2 + p_{T,\bar{t}}^2} \right)^{1/2}, \]  

(3.9)
where the top and anti-top transverse momenta are reconstructed from their decay products based on Monte Carlo truth. Note that the determination of the top momentum is subject to an ambiguity, since it can be reconstructed by two different lepton–neutrino pairs: we choose the pair that, combined with the b quark, gives rise to an invariant mass which is the closer to \( m_t \). This scale choice is motivated by the expectation that top–antitop resonances dominate the cross-section, even when considering complete off-shell effects.

Finally, we consider some results for the scale choice

\[
\mu_0^{(e)} = (M_{t,\perp} M_{\bar{t},\perp})^{1/2}/2,
\]

(3.10)

In Table 1 we show the integrated cross-sections for the four scale choices, complemented with the corresponding scale uncertainties, evaluated with 7-point scale variations, namely rescaling the central factorisation and renormalisation scale by the factors

\[
(0.5, 0.5), (1, 0.5), (0.5, 1), (1, 1), (1, 2), (2, 1), (2, 2).
\]

We have checked that the largest scale variations result from varying the renormalisation scale. At LO the fiducial cross-sections computed with \( \mu_0^{(b)} \) and \( \mu_0^{(d)} \) differ by less than 1% and are about 6% smaller than the results with fixed scale \( \mu_0^{(a)} \). The scale \( \mu_0^{(c)} \) gives a cross-section which is 6% higher than the one obtained with the fixed scale, while the one for \( \mu_0^{(c)} \) is even 16% larger. In all cases the scale uncertainties are of the same size, i.e. approximately 20% relative to the central value. The QCD corrections amount to +20% for the fixed scale. While the scale \( \mu_0^{(b)} \) yields almost the same \( K \)-factor, the corrections are larger for \( \mu_0^{(d)} \) (+25%) and smaller for \( \mu_0^{(c)} \) (+13%) and \( \mu_0^{(e)} \) (+7%). At NLO QCD, all scale choices give scale uncertainties of the order of 5% with some small differences in the various cases. In particular, the use of \( \mu_0^{(c)} \) or \( \mu_0^{(e)} \) entails slightly smaller scale uncertainties compared to the fixed scale, while those of \( \mu_0^{(d)} \) are larger. These differences are more sizeable at the differential level, as is shown in the following.

In Fig. 5 we show the scale dependence of the fiducial cross-section for the four scale choices introduced in Eqs. (3.7)–(3.9). The factorisation and renormalisation scales are

| \( \mu_0 \) | LO | NLO QCD | \( K \)-factor |
|---|---|---|---|
| \( (a) \) \( m_t + M_W/2 \) | \( 0.2042(1)^{+0.0485(23.8\%)}_{-0.0367(18.0\%)} \) | \( 0.2452(7)^{+0.0109(4.5\%)}_{-0.0166(6.8\%)} \) | 1.20 |
| \( (b) \) \( H_T/2 \) | \( 0.1931(1)^{+0.0444(23.0\%)}_{-0.0339(17.5\%)} \) | \( 0.2330(9)^{+0.0098(4.2\%)}_{-0.0152(6.5\%)} \) | 1.21 |
| \( (c) \) \( H_T/3 \) | \( 0.2175(1)^{+0.025(24.2\%)}_{-0.03096(18.2\%)} \) | \( 0.2462(8)^{+0.0069(2.8\%)}_{-0.0143(5.8\%)} \) | 1.13 |
| \( (d) \) \( (M_{t,\perp} M_{\bar{t},\perp})^{1/2} \) | \( 0.1920(1)^{+0.0444(23.0\%)}_{-0.0336(17.5\%)} \) | \( 0.2394(6)^{+0.0129(5.4\%)}_{-0.0172(7.2\%)} \) | 1.25 |
| \( (e) \) \( (M_{t,\perp} M_{\bar{t},\perp})^{1/2}/2 \) | \( 0.2360(1)^{+0.0591(24.9\%)}_{-0.0441(18.7\%)} \) | \( 0.2535(5)^{+0.0086(3.4\%)}_{-0.0133(5.2\%)} \) | 1.07 |

Table 1. Fiducial cross-sections (fb) for fixed and dynamical scale choices defined in this section. The uncertainties have been computed with 7-point scale variations around the central value.
varied simultaneously scaling the central value \( \mu_0 \) by a factor \( \xi = 1/8, 1/4, 1/2, 1, 2, 4, 8 \). At LO, \( \mu_0^{(b)} \) and \( \mu_0^{(d)} \) give almost identical cross-sections for any \( \xi \) factor, which are roughly 5% smaller than the corresponding results with fixed scale \( \mu_0^{(a)} \). On the contrary, the scale \( \mu_0^{(c)} \) gives a +6% enhancement to the LO cross-sections with respect to the fixed scale. At NLO QCD, for \( \xi > 1 \), the cross-section computed with \( \mu_0^{(a)} \) takes intermediate values between the corresponding value for \( \mu_0^{(c)} \) (+7%) and for \( \mu_0^{(d)} \) (−7%). The scale \( \mu_0^{(b)} \) behaves similarly to \( \mu_0^{(d)} \). At small values of the scales, \( \xi < 1 \), the behaviour of the results for \( \mu_0^{(c)} \) and \( \mu_0^{(d)} \) is inverted: for the former the cross-section becomes noticeably lower than the one for fixed scale, while for the latter it becomes larger. Differently from \( \mu_0^{(d)} \), the results obtained with \( \mu_0^{(b)} \) for \( \xi < 1 \) remain lower than those obtained with \( \mu_0^{(a)} \). Comparison of the different curves suggests that the results for the choice \( \mu_0^{(e)} = \mu_0^{(d)}/2 \) for the central scale would be close to those for \( \mu_0^{(c)} \), in particular for \( \xi > 1 \). On the one hand, this choice would reduce the corresponding scale dependence, shift the central scale towards the maximum of the curve in a similar way as going from \( \mu_0^{(b)} \) to \( \mu_0^{(c)} \), and would lead to a smaller \( K \)-factor. On the other hand, \( \mu_0^{(d)} \) corresponds to the choice made in calculations for on-shell tops.

### 3.3 Differential cross-sections

Beyond integrated cross-sections, it is of crucial importance to study how NLO QCD corrections affect the distributions in the relevant kinematic variables. This is the aim of this section. We start by comparing distributions obtained with different central-scale choices in Section 3.3.1 and the corresponding scale variation of the relative corrections. Thereafter we present more results for the dynamical scale \( \mu_0^{(d)} \) in Section 3.3.2.

#### 3.3.1 Comparison of different central-scale definitions

Motivated by the results obtained at the integrated level, we are not showing any result for \( \mu_0^{(b)} \). The focus is put on the differences between the results obtained with the fixed scale and those obtained with \( \mu_0^{(c)} \) and \( \mu_0^{(d)} \), as we expect that the choice of a well-motivated
dynamical scale is beneficial for a better behaviour of NLO QCD corrections, in particular, in the tails of energy-dependent distributions. This is indeed the case for the transverse-momentum distributions for the positron and the reconstructed top quark, which are shown in Fig. 6 and Fig. 7, respectively.

![Figure 6](image1.png)

(a) Fixed scale $\mu_0^{(a)} = m_t + M_W/2$.
(b) Dynamical scale $\mu_0^{(d)} = (M_{T,t} M_{T,\bar{t}})^{1/2}$.

**Figure 6.** Distributions in the transverse momentum of the positron at LO and NLO QCD: differential cross-sections (upper plot) and $K$-factor (lower plot). The uncertainty bands have been computed by means of 7-point variations of the factorisation and renormalisation scale around the central scale.

![Figure 7](image2.png)

(a) Fixed scale $\mu_0^{(a)} = m_t + M_W/2$.
(b) Dynamical scale $\mu_0^{(d)} = (M_{T,t} M_{T,\bar{t}})^{1/2}$.

**Figure 7.** Distributions in the transverse momentum of the reconstructed top quark at LO and NLO QCD: differential cross-sections (upper plot) and $K$-factor (lower plot). The uncertainty bands have been computed by means of 7-point variations of the factorisation and renormalisation scale around the central scale.
Comparing Fig. 6(a) with Fig. 6(b), it can be seen that using the fixed scale leads to a differential $K$-factor that drops monotonically from 1.25 to 0.95 with increasing transverse momentum of the positron. On the contrary, the dynamical scale gives a $K$-factor that decreases only from 1.3 to 1.1. Differently from the case of fixed scale, the scale uncertainties do not decrease for the dynamical scale in the tails of the distribution. Using the scale $\mu_0^{(c)}$, the $K$-factor becomes somewhat flatter, but the scale uncertainties are similar.

The same situation can be found in the comparison of Fig. 7(a) and Fig. 7(b). The transverse momentum of the top quark considered in Fig. 7 refers to the top quark reconstructed using Monte Carlo truth from the bottom quark and the $\ell^+\nu_\ell$ pair that gives an invariant mass which is the closest to $m_t$ (denoted “$\ell^+ \text{best}$” in the following). While not measurable at the LHC, it is interesting to investigate this observable as it is directly related to the dominant resonant structure of the process, i.e. the top and antitop quarks. While the $K$-factor for the fixed scale drops from 1.35 to 0.9, it is practically flat for the dynamical scale $\mu_0^{(d)}$. While the NLO uncertainty bands are similar in the two cases in the soft part of the spectrum they are sizeably larger for the dynamical scale at large transverse momentum. Again, the results are similar for the scale $\mu_0^{(c)}$, where the $K$-factor varies from 1.20 to 1.12.

Given the flatness of the $K$-factors of Figs. 6 and 7, we can conclude that using the dynamical scale $\mu_0^{(d)}$ or $\mu_0^{(c)}$ results in better behaved NLO QCD corrections than with the fixed scale.

In Fig. 8 we consider the distribution in the $H_T$ variable comparing the results obtained with the two dynamical scales $\mu_0^{(d)}$ and $\mu_0^{(c)}$. The dynamical scale $\mu_0^{(d)}$, which depends on the top–antitop transverse masses, describes very well the $H_T$ variable at NLO QCD, with a $K$-factor varying between 1.1 and 1.35. Furthermore, the $K$-factor has a similar shape...
and variation as the one obtained with $\mu_0^{(c)}$, which coincides with the variable itself up to the $1/3$ multiplicative factor. The most relevant difference between the two scales is given by a constant shift of the $K$-factor to larger values in the $\mu_0^{(d)}$ case resulting from the difference of the integrated cross-section (see Table 1). The NLO uncertainty bands are marginally larger for $\mu_0^{(d)}$ for moderate values of $H_T$. We have checked numerically that the uncertainty bands for $\mu_0^{(e)}$ are comparable to those for $\mu_0^{(c)}$.

Since analogous similarities between the two scale choices can be found in the distributions for many other kinematic variables that we have investigated, we conclude that the quality of the NLO description of the process at the differential level is comparable for the two dynamical scale choices. Therefore, in all results we are going to present in the following, $\mu_0^{(d)}$ is understood as a central factorisation and renormalisation scale.

3.3.2 Differential distributions for the default scale

In this section we discuss LO and NLO QCD results for selected differential cross-sections, including both angular and energy-dependent variables. We consider not only observables that are directly measurable at the LHC, but also kinematic variables related to the top and antitop resonances based on Monte Carlo truth. The explicit final state that we consider enables to sort charged leptons by their flavour, with no need of a transverse-momentum ordering. However, in order to be useful for final states with identical leptons, we also compute some observables based on the transverse-momentum ordering of the positively-charged leptons, as needed in the case of identical positrons [36]. We denote leptons or bottom quarks with highest transverse momenta as leading ones in the following. Moreover, we also sort the two positively-charged leptons $e^+, \tau^+$ depending on how well they reconstruct the true top-quark invariant mass, as already done in the previous sections for the computation of the $\mu_0^{(d)}$ central scale.

In Fig. 9 we show the LO and NLO distributions and $K$-factors for the azimuthal-angle separations between the leading $b$ jet and the leading positively-charged lepton [both sorted by their $p_T$, Fig. 9(a)] and between the positron and the muon [Fig. 9(b)]. The relative corrections for the two distributions behave similarly. In fact, the $K$-factors are of order 50% in the region with smaller cross-section ($\Delta\phi \approx 0$) and decrease to 15% towards $\Delta\phi = \pi$, where both distributions show a maximum. While the NLO uncertainty bands are almost as wide as the LO ones at low azimuthal separation, they become noticeably smaller in the peak region. We note that the distributions in the azimuthal separation between the antitau and the muon (which are not shown here) have exactly the same shape and normalisations as those shown in Fig. 9(b), since the leptonic decay of the $W^+$ boson is universal and the symmetry under the exchange of the two leptonically decaying $W^+$ bosons is accounted for in the full amplitudes. This comment holds for any variable that depends on the kinematics of a single positively-charged lepton selected by its flavour.

A slightly different situation is found for the distribution in the cosine of the angle between the two positively charged leptons, shown in Fig. 10(a). This variable correlates the two charged leptons which are decay products of the two $W^+$ bosons, i.e. one of them comes from the top-quark decay and the other one from the $W^+$ boson recoiling against the $t\bar{t}$ system. The NLO corrections are positive over the whole spectrum, and inherit the
Figure 9. Distributions at LO and NLO QCD for the dynamical scale choice: differential cross-sections (upper plot) and $K$-factor (lower plot). The uncertainty bands have been computed by means of 7-point variations of the factorisation and renormalisation scale around the central scale.

Figure 10. Same as in Fig. 9.

relative increase in the cross-section from the integrated results (+25%). The $K$-factor decreases from 1.4 in the back-to-back configuration to 1.2 in the collinear case. The minimum of the NLO distribution is shifted from $\cos \theta_{e^+e^-} \approx -0.35$ (at LO) to $-0.2$, and the two local maxima are in the collinear and anticollinear configurations: the former configuration is preferred, even though NLO corrections are larger for the latter.

In Fig. 10(b) we consider the distribution in the invariant mass of the system formed by
the positron and the leading b jet. The distribution exhibits a maximum around 100 GeV and a marked drop around 150 GeV. For on-shell W boson and top quark, this variable has an upper bound at $M_{e^+b}^2 = m_t^2 - M_W^2$. As the considered variable depends on the leading b jet, which is not necessarily the bottom quark that originates from the top quark, the drop is not as pronounced as it would be in the absence of this ambiguity. Nevertheless, the edge is present in the considered process and could help to increase the experimental sensitivity to the top-quark mass. In the on-shell region, $M_{e^+b} < 150$ GeV, the NLO QCD corrections mildly decrease from 30% to 25%, while in the off-shell region, $M_{e^+b} > 150$ GeV, they basically reflect the overall normalisation with an almost flat $K$-factor, up to small statistical oscillations in the tails of the distribution where the rate is exponentially damped. The NLO uncertainty bands are of order 5% in the part of the spectrum with a higher rate, while they increase to 15% in the tails.

In Fig. 11 we present the distributions in the rapidities of the positron and the antitop quark. The first distribution is measurable, while the second one is based on Monte Carlo truth. The positron rapidity is directly cut at $y_{e^+} = \pm 2.5$, while the one of the antitop gives an almost negligible contribution for $|y_{\bar{t}}| > 2.5$. Despite having similar behaviours at LO, the effect of QCD radiative corrections is different in the two variables. In the positron case, the radiative corrections are maximal in the region close to the acceptance cut (roughly +50%), while they are smaller near the peak of the distribution (+20% for $y_{e^+} = 0$). In contrast, the radiative corrections give a maximal enhancement to the antitop distribution around the peak at zero rapidity (+35%), while they are almost zero at large rapidities.

In Figs. 12(a) and 12(b), we analyse the distributions in the invariant masses of the antitop quark and the reconstructed top quark, respectively. The top quark is reconstructed according to the above-described requirement that the selected $\ell^+\nu_\ell$ pair gives the invariant mass closest to $m_t$ when combined with the b-quark jet. In both cases, the NLO corrections
are very large and positive below the top mass. For a reconstructed mass of $m_t - 25$ GeV, the NLO cross-section is one order of magnitude larger than the LO one. This radiative tail is due to final-state gluon radiation which is not recombined with the decay products of the antitop or top resonance. At the peak, the NLO corrections are small and negative ($-10\%$). In the off-shell region above the pole mass they become again large and positive, reaching $\approx +100\%$ at $m_t + 25$ GeV for the reconstructed top quark. The relative corrections are more moderate for the antitop mass ($\approx 70\%$) in the same region owing to the absence of the reconstruction ambiguity which affects the top quark in the considered process. The general features of the correction to this distribution are similar as for top–antitop production [74].

As already seen in Fig. 12, not all distributions receive NLO $K$-factors that are close to the value of 1.25 for the fiducial cross-section. In Fig. 13 we consider two more observables that experience very large NLO corrections in the tails of distributions, the transverse momentum of the $t\bar{t}$ system (depending on the reconstructed top quark) and the transverse momentum of the two $b$-jet system shown in Fig. 13(a) and Fig. 13(b), respectively. The transverse momentum of the top–antitop system is equivalent to the transverse momentum of the recoiling system formed by a $W^+$ boson and the additional light jet that may arise at NLO. The presence of a large real-radiation contribution explains the huge QCD corrections, which are of order $+200\%$ for values larger than 500 GeV. In this region the relative scale uncertainties are larger than the LO ones, since the dominant scale uncertainty arises from the real corrections of order $\alpha_s^3$ which have only LO accuracy. In the soft region of the spectrum the NLO corrections become negative. The transverse momentum of the $b\bar{b}$ system (which is measurable at the LHC) is less directly affected by the additional QCD radiation at NLO. For $p_{T,b\bar{b}} < 150$ GeV the $K$-factor stays almost constant around $+20\%$, while for larger values it increases, exceeding $+100\%$ for $p_{T,b\bar{b}} > 300$ GeV. Also this large effect is due to the sizeable contribution of the real radiation which is not clustered into any
of the two b jets. As for the t¯t system, the scale uncertainties are large in the tails of the distribution, as they are dominated by only LO accurate real radiation. We have checked that the differential K-factors and scale uncertainties for the two transverse-momentum distributions practically do not change if either µ(c)0 or µ(e)0 is used as a central scale.

### 3.4 Comparison with double-pole approximation

In the previous section we have investigated differential variables related to the top and antitop resonances of the process as well as variables that are measurable at the LHC, without having any direct connection to the dominant resonances.

Since performing the full computation is demanding from the computational point of view, approximated calculations are often used. For them, a proper validation is mandatory as they usually rely on on-shell approximations, which could in principle be far from reproducing the off-shell structure of the simulated processes.

In this section we compare integrated and differential results obtained with the full off-shell computation and those obtained with two different variants of the DPA described in Section 2.3. In one approach, we have applied the DPA to the virtual contributions only, obtaining impressive agreement with the full results. Alternatively, we have applied it both to the virtual corrections and to the αdipole-independent contributions of I-operators (see Section 2.3).

In Table 2 we show the different contributions to the fiducial NLO cross-sections, computed with full matrix elements and with the DPA. The DPA underestimates the Born cross-section by 2.7%. Since the deviations from the full results can be very large in some kinematic regions, we are not showing differential distributions at Born level. The virtual contributions are very well described by the DPA, while the αdipole-independent and αdipole-dependent terms of the I-operators (which take negative values) are reproduced with 2.8%
Table 2. Contributions to the fiducial NLO cross-sections (fb), obtained with the off-shell calculation and with the DPA. The central scale \( \mu^{(d)}_0 \) is understood. Numerical uncertainties are shown in parentheses. The value \( \Delta_{\text{DPA}} \) is computed as the difference between the DPA and the full results normalised to the full one.

| contribution | full          | DPA           | \( \Delta_{\text{DPA}} \) |
|--------------|---------------|---------------|-----------------------------|
| B (Born, with NLO PDFs) | 0.20326(4)    | 0.19770(3)    | -2.7%                       |
| V (virtual)  | -0.02079(5)   | -0.02071(3)   | -0.4%                       |
| I (integrated dipoles, \( \alpha_{\text{dipole}} \)-independent \( I \)-operator) | -0.1004(1)    | -0.0976(1)    | -2.8%                       |
| I (integrated dipoles, \( \alpha_{\text{dipole}} \)-dependent \( I \)-operator, \( \alpha_{\text{dipole}} = 0.01 \)) | -0.3276(3)    | -0.3204(3)    | -2.2%                       |
| I (integrated dipoles, K, P-operators, \( \alpha_{\text{dipole}} = 0.01 \)) | 0.1682(2)     | –             | –                           |
| R (real subtracted) | 0.3167(5)     | –             | –                           |

and 2.2% negative deviation, respectively, similarly to the LO contributions and of the expected order \( \Gamma_t/m_t \).

The fiducial NLO cross-sections obtained with the full off-shell and the two DPA calculations read:

\[
\sigma_{\text{NLO}}^{\text{full}} = 0.2394(6) \text{ fb}, \quad \sigma_{\text{NLO}}^{\text{DPA}, \text{V}} = 0.2395(7) \text{ fb}, \quad \sigma_{\text{NLO}}^{\text{DPA}, \text{V+I}} = 0.2422(7). 
\]

The variant of the DPA that approximates only the finite virtual corrections reproduces the full result very well and within integration errors. This is due to the fact that the finite virtual corrections contribute less than 10% to the NLO fiducial cross-section. Note, however, that the difference turns out to be somewhat smaller than the intrinsic uncertainty of the DPA, which is \( 10\% \times \Gamma_t/m_t \approx 0.1\% \), and is within the integration error. Applying the DPA also to the \( \alpha_{\text{dipole}} \)-independent integrated-dipole contributions worsens the agreement and leads to a cross-section that is 1.2% larger than the full one. This is due to the fact that the integrated dipoles make up 50% of the NLO cross-section. Treating also the \( \alpha_{\text{dipole}} \)-dependent integrated-dipole contributions within the DPA, would deteriorate the accuracy even more since these contributions are even larger but cancel to a large extent with the real subtracted contributions that are not treated with the DPA (see Table 2). This option is not considered any further in this paper. The percent-level discrepancy between \( \sigma_{\text{NLO}}^{\text{DPA}, \text{V+I}} \) and \( \sigma_{\text{NLO}}^{\text{full}} \) translates to even larger discrepancies when looking at exclusive phase-space regions.

In Fig. 14 we consider the transverse-momentum and invariant-mass distributions of the two-b-jet system. Discrepancies at the level of 5% can be found in the tails of the two distributions, though with opposite signs, when approximating the virtual corrections. The DPA gives a larger NLO cross-section in the large-transverse-momentum regime and
Figure 14. Differential distributions at NLO QCD, obtained with full matrix elements, and applying the DPA either to the virtual contributions only, or both to the virtual and to the $\alpha_d$-independent part of $I$-operators. The dynamical scale $\mu_0^{(d)} = (M_{T_1} M_{T_n})^{1/2}$ is understood. Differential cross-sections are shown in the upper plot, the ratio over the full result in the lower plot.

a smaller one for large invariant masses. In Ref. [36], an analogous effect of even 20% has been found in the invariant-mass spectrum using the narrow-width approximation. Applying the DPA also to the integrated dipoles shifts the results towards larger values in the tails of both distributions, resulting in a +10% deviation for $p_{T,b\bar{b}} = 600$ GeV, and in a deviation of 2% at large invariant mass ($M_{b\bar{b}} > 200$ GeV). In the tails of the distributions, the relative contribution of integrated dipoles to the cross-section is even larger than at the integrated level.

To investigate how well the top-quark resonance is reproduced within the DPA, we consider the distribution in the invariant mass of the positron–electron–neutrino–bottom system, $M_{e^+\nu_e b}$, and of the reconstructed (with the same criterion as used in the previous sections) top quark in Fig. 15. The DPA applied to virtual corrections only leads to a result that is slightly smaller (larger) than the full one for invariant masses below (above) the top-quark mass. However, this effect is very small (at most 1%) for both variants of the reconstructed top quark mass. Applying the DPA to integrated dipoles affects the two distributions differently for values larger than $m_t$. For $M_{e^+\nu_e b}$, the DPA result is 5% larger than the full result in this region, while choosing the reconstructed top-quark mass gives a larger deviation reaching +13% for $M_{t_{\text{best}}} = m_t + 20$ GeV. The large deviations appear in the off-shell region above the top resonance in which the resonant contributions are suppressed. The effect is smaller in Fig. 15(a) because of the background of about half of the events, where the resonant top-quark decays to $b\tau^+\nu_\tau$.

The distribution in the $H_T$ observable is considered in Fig. 16(a). The DPA calculation gives a relevant enhancement to the off-shell result in the tail of the distribution. The size of this effect for $H_T > 1600$ GeV is 3% if the DPA is applied only to the vir-
(a) Invariant mass of the positron–electron–neutrino–bottom system.

(a) $H_T$ variable, excluding additional radiation.

(b) Transverse momentum of the antitop quark.

**Figure 16.** Same as in Fig. 14.

tual contributions and 7% if it is applied also to the integrated dipoles. The deviation has some similarities with the one observed in the $b\bar{b}$ system transverse momentum [see Fig. 14(a)]. The $H_T$ variable has been studied in Ref. [36], finding that the narrow-width approximation underestimates the full cross-section for large $H_T$ by some 30%, going in the opposite direction with respect to the DPA technique we consider here. This highlights that approximated computations should be taken with a grain of salt, and must be verified with results based on full matrix elements, in particular, in regions of phase space where non-doubly-resonant contributions are not suppressed.

As a last example, we show the distributions in the antitop-quark transverse momen-
tum in Fig. 16(b). This variable is well described by the DPA in the whole spectrum, even in the tail. The discrepancy between the two DPA curves and the full one is roughly constant and reflects the results at the integrated level. This illustrates that the DPA works very well also at the differential level for kinematic variables that are directly related to the antitop or top quark. Both for the DPA applied to only the virtual corrections and the DPA applied also to the contributions of the $I$-operators the relative deviations from the off-shell results are flat and of the same size as for the fiducial cross-section.

4 Conclusions

In this paper, we have presented the calculation of NLO QCD corrections to the off-shell production of a top–antitop-quark pair in association with a $W^+$ boson, considering a final state with three charged leptons, two b jets and missing energy. Although our results have been obtained for the specific case of three different lepton flavours, they hold to good approximation also for the case of two identical positively-charged leptons up to a global symmetry factor $1/2$. All non-resonant effects, interferences, as well as spin correlations are accounted for in all parts of the computation. We have studied both integrated and differential cross-sections, and performed a comparison between the results obtained from full matrix elements and using a double-pole approximation (DPA).

We have investigated different choices of the central factorisation and renormalisation scale, both fixed and dynamical. We have found that employing a dynamical scale gives better-behaved NLO QCD predictions than using the fixed scale $\mu_0 = m_t + M_W/2$. This holds both for a scale based on the transverse-momentum content of the final state, $\mu_0 = H_T$, and for a scale based on the transverse masses of the dominant top–antitop resonances, $\mu_0 = (M_{t,T} M_{\bar{t},T})^{1/2}$.

Considering proton–proton collisions at a 13 TeV, the QCD corrections with a dynamical scale choice are positive and moderate (+25%) at the integrated level. The theoretical uncertainties estimated from scale variations decrease from 20% at LO to 5% at NLO. Corrections for distribution become larger than those for the fiducial cross-section in several phase-space regions, in particular, in the tails of energy-dependent distributions which depend on the hadronic activity (b jets, additional QCD radiation), both for measurable LHC observables and for variables based on Monte Carlo truth describing the top and antitop resonances. The scale uncertainties are of the same or even larger size than the LO ones in the tails of certain transverse-momentum and invariant-mass distributions.

The DPA reproduces in a surprisingly accurate manner most results of the calculation based on full matrix elements if applied only to the virtual corrections, thanks to the relatively small size of such contributions. When the DPA is applied also to the integrated subtraction counterterms ($I$-operators in the Catani–Seymour scheme), it reproduces the full results at the 1% level for the fiducial cross-section and top-dependent observables, while deviations of a few percent are found in more exclusive parts of the phase space, in agreement with the intrinsic uncertainty of the approximation. However, in regions of phase space that are not dominated by top–antitop production, the discrepancy can reach 10% and more.
In conclusion, the calculation presented in this paper represents an important step towards a precise theoretical description of $t\bar{t}W$ production, which will be beneficial both in direct searches and in the background modelling for other relevant signals at the LHC. Since off-shell $t\bar{t}W$ production is dominated by contributions from top and antitop resonances, the approximated calculation relying on the resonant contributions is expected to give a reasonable picture of the process in sufficiently inclusive phase-space regions. However, given the increased luminosity that will be available in the next LHC runs, in view of a precise and fully trustworthy comparison between experimental data and theoretical predictions, the calculation based on full matrix elements is strongly recommended, as it gives a more complete description of the process in inclusive and exclusive kinematic regions.
