Abstract. We study some new universal aspects of diffusion in chaotic systems, especially such having very large Lyapunov coefficients on the chaotic (indecomposable, topologically transitive) component. We do this by discretizing the chaotic component on the Surface-of-Section in a (large) number $N$ of simplistically equally big cells (in the sense of equal relative invariant ergodic measure, normalized so that the total measure of the chaotic component is unity). By iterating the transition of the chaotic orbit through SOS, where $j$ counts the number of iteration (discrete time), and assuming complete lack of correlations even between consecutive crossings (which can be justified due to the very large Lyapunov exponents), we show the universal approach of the relative measure of the occupied cells, denoted by $\rho(j)$, to the asymptotic value of unity, in the following way: $\rho(j) = 1 - (1 - \frac{1}{N})^j$, so that in the limit of big $N$, $N \to \infty$, we have, for $j/N$ fixed, the exponential law $\rho(j) \approx 1 - \exp(-j/N)$. This analytic result is verified numerically in a
variety of specific systems: For a plane billiard (Robnik 1983, $\lambda = 0.375$), for a 3-D billiard (Prosen 1997, $a = -1/5, b = -12/5$), for ergodic logistic map (tent map), for standard map ($k = 400$) and for hydrogen atom in strong magnetic field ($\epsilon = -0.05$) the agreement is almost perfect (except, in the latter two systems, for some long-time deviations on very small scale), but for Hénon-Heiles system ($E = 1/6$) and for the standard map ($k = 3$) the deviations are noticed although they are not very big (only about 1%). We have tested the random number generators (Press et al 1986), and confirmed that some are almost perfect (ran0 and ran3), whilst two of them (ran1 and ran2) exhibit big deviations (in units of the theoretically expected standard deviation, as much as 20). Thus physical deterministic chaotic systems can be better simulators of random numbers than some well known mathematical algorithms. We give an outline of an improved analytical theoretical model (the so-called two and many component model), where deviations from the exponential law can be captured in a statistical way.

Submitted to Journal of Physics A: Mathematical and General
One of the major open problems in the mathematics of nonlinear Hamiltonian (conservative) chaotic systems of the KAM type is the proof of the so-called coexistence problem (Strelcyn 1991), i.e. the proof that the chaotic components have positive measure. (The KAM Theorem guarantees that the set of invariant tori has positive measure, whose complement is small with the perturbation parameter (Kolmogoroff 1954, Arnold 1963, Moser 1962, Benettin et al 1984, Gutzwiller 1990).) The chaotic component could be defined e.g. by the positivity of the (largest) Lyapunov exponent, which is a sufficient but not a necessary criterion\footnote{For example, in nonrational plane polygonal billiards all Lyapunov exponents are strictly zero (Sinai 1976), and yet they can be ergodic.}. We shall define a chaotic component as the closure of a dense chaotic orbit, which is thus assumed to be an indecomposable invariant component (topologically transitive, i.e. containing a chaotic dense orbit).

There are really no serious doubts about the positivity of the measure of the chaotic components, and so in physics we rely on heuristic arguments to actually assume positivity. Then the question is how to calculate the symplectic (invariant and ergodic) measure of the chaotic component.

We have approached this problem in a recent extensive work (Dobnikar 1996, Robnik and Dobnikar 1997) on the dynamics in a plane billiard system, defined as the quadratic conformal map of the unit disc (in the complex z-plane) onto the physical (complex) w-plane, \( w(z) = z + \lambda z^2 \). This system has been introduced by Robnik (1983), and recently extensively studied for many different values of \( \lambda \) by many authors, in a variety of contexts and even in experimental setups like quantum dots (Bruus and Stone 1994, Stone and Bruus 1993ab), optical model (Nöckel and Stone 1997, Nöckel et al 1996), microwave cavities (Rehfeld et al 1996, Richter 1996, Stöckmann et al 1997). Further dynamical details were corrected in (Hayli et al 1987).

At \( \lambda = 0 \) we have the integrable case of the circle billiard, for \( 0 < \lambda < 1/4 \) the billiard is convex, and since the boundary is analytic, the KAM theory applies (Lazutkin 1981, 1991), at \( \lambda = 1/4 \) we get the first point of zero curvature at the boundary point \( w = w(z = -1) = -3/4 \), allowing for the breaking of Lazutkin caustics (invariant tori associated with the boundary
glancing orbits), and for $1/4 < \lambda < 1/2$ the billiard is non-convex, largely and strongly chaotic (very tiny islands of stability), probably becomes rigorously ergodic at some $\lambda \geq 0.2775$ (Li and Robnik 1994), and is definitely proven to be rigorously ergodic for $\lambda = 1/2$ (the so-called cardioid billiard, having the cusp singularity at $w = w(z = -1) = -1/2$) (Markarian 1993). The cardioid billiard has been studied also by Bäcker, Steiner and Stifter (1995) and by Bäcker and Dullin (1997).

Our main problem was to calculate numerically, accurately and reliably, the measure of chaotic components. Working in the KAM regime ($0 < \lambda < 1/4$) we were observing the typical KAM hierarchy of smaller and smaller islands of stability surrounded by chaotic components, the details of which will be reported in a separate paper (Robnik and Dobnikar 1997), but are reported already in (Robnik 1983).

The main objective was to calculate the fractional measure (the relative area on the SOS, the latter being defined by the Poincaré-Birkhoff coordinates) of the largest chaotic component at given $\lambda$, which we traditionally denote by $\rho_2$.

This parameter is important also in treating the related quantum mechanical problem (solutions of the Helmholtz equation with the Dirichlet boundary conditions on the billiard boundary) (Berry and Robnik 1984, Prosen and Robnik 1993,1994a-b, Li and Robnik 1995).

We have discovered, to our big surprise, that this numerical calculation is extremely difficult, and as one consequence, some of the previous results had to be revised. By dividing the SOS into a large number of rectangular grid cells of equal relative (normalized) measure we have calculated the relative measure of the chaotic component $\rho_2$ by three different methods: (M1) calculating the Lyapunov exponent for a trajectory starting in a given cell and summing up the area of cells having the positive Lyapunov exponent; (M2) calculating two nearby trajectories, separated by an infinitesimal distance (e.g. single precision e-8 while all calculations were in double precision e-16) and summing the cells exhibiting macroscopic divergence in a reasonable time; and (M3) starting the chaotic trajectory and counting (summing up) the area of the cells visited ("black cells").

It turned out that the third method (M3) is the best, fastest, and most reliable. To improve the result one has to enlarge the number of cells $N$ on the chaotic component. But then, the time $j$ (of iterating the map on
the SOS, the discrete time) has to be taken much larger (by at least several orders of magnitude) than $N$, otherwise the statistics of visiting cells (black cells) would be insignificant. Even after calculating as many as $10^9$ iterations, with $N = 1000 - 2000$, the result was no better than within 1%. One reason is that the boundary of the chaotic component turned out to have relatively large fractal dimension around 1.56. The difficulties of estimating the asymptotic value of the relative area $\rho_2$ of the chaotic component led us to the careful investigation of the evolution of relative area of occupied (black) cells $\rho_2(j)$ as time $j$ proceeds, and we wanted to understand that theoretically, in order to be able to make better estimates of the limiting asymptotic value $\rho_2 \equiv \rho_2(j = \infty)$. From here onwards we shall use the notation $\rho(j) \equiv \rho_2(j)/\rho_2(j = \infty)$.

In general this time evolution $\rho(j)$ with $j$ is quite complex and specific, nonuniversal, depending on many features appearing in the phase space (SOS), e.g. existence of sticky objects like cantori can affect a temporary but quite persistent trapping of the orbit near such an object, which is then manifested in a transient plateau of the curve $\rho(j)$, which sometimes might be mistakenly interpreted as final and definite convergence of the cumulative area/volume $\rho_2(j)$. However, if the system is really strongly chaotic, having large maximal positive Lyapunov exponent, then due to the bound motion and conservation of the phase space volume, we find a very strong stretching and folding in the phase space. In such a limiting case therefore one small phase space cell (SOS cell) becomes uniformly distributed, in the coarse grained sense, all over the allowed chaotic component. Thus, in such extreme case, the probability of entering a given cell belonging to the same chaotic component in SOS is just equal to the relative measure of the cell, i.e. there are no correlations, not even between two consecutive SOS iterations: complete randomness of deterministic motion.

While the behaviour in such ideal extreme case is quite obvious, it is far from obvious that the conditions of the complete randomness are actually satisfied in specific chaotic deterministic dynamical systems. Therefore, to make things precise we have developed the following theoretical model.

Suppose we have $N$ cells, where their order and geometry of arrangement is completely irrelevant and perhaps not even known. We are filling the cells
with balls, one at the time. At each step $j$ (discrete time) we have equal probability to choose any cell, equal to $a \equiv 1/N$. (Thus there are absolutely no correlations between any moves, including the consecutive ones, and therefore e.g. the repetition of falling into a given already filled cell is allowed.) We define by $P_j(k)$ the probability that at $j$-th step $k$ cells are occupied, keeping in mind that $a = 1/N$ is the model parameter implicit in the mathematical formulae. We shall refer to this model as the random model (of strongly chaotic deterministic diffusion). The probabilities must be normalized, therefore

$$\sum_{k=1}^{k=N} P_j(k) = 1, \quad \forall j = 1, 2, \ldots. \quad (1)$$

We shall calculate $P_j(k)$, and their moments, in particular the first moment, namely the average (normalized) measure of the occupied cells,

$$\rho(j) \equiv \sum_{k=1}^{N} kaP_j(k) = \langle ka \rangle, \quad (2)$$

where by $\langle ... \rangle$ we denote the averaging operation.

Before explicitly calculating $P_j(k)$ we observe the physically (probabilistically) quite obvious recursion relation, namely

$$P_{j+1}(k+1) = P_j(k+1) \frac{k+1}{N} + P_j(k)(1 - \frac{k}{N}), \quad \forall 0 \leq k \leq j, \quad (3)$$

where we also define the boundary conditions

$$P_j(0) \equiv 0, \quad P_1(1) = 1, \quad P_j(k > j) = 0, \quad P_j(k > N) = 0. \quad (4)$$

The interpretation of equation (3) is: the probability to have $(k+1)$ cells occupied at time $(j+1)$ is equal to the sum of the following probabilities: either at time $j$ the $(k+1)$ cells were already occupied, and we add the next ball into the black cells with probability $(k+1)/N$, or at time $j$ only $k$ cells are occupied (black), and we add the next ball (the $(j+1)$-st one) into the empty (not-yet-occupied) cells with probability $(1 - k/N)$. With
the boundary conditions (3) the recursion relation (3) solves the problem, in principle. We show the explicit solution below, using different approach. However, for a practical (numerical) evaluation of \( P_j(k) \) (on the computer) it is much better to use the recursion formula (3) than the explicit result which we shall derive below.

For the beginning please observe that the summation of the recursion equation (3) on each side from \( k = 0 \) to \( k = N - 1 \) confirms the preservation of normalization (1), for all \( j \).

Next, we can find the solution for \( \rho(j) \) at once by the following trick: multiply the recursion relation (3) on the left and on the right by \((k + 1)/N\) and sum it from \( k = 0 \) to \( k = N - 1 \). By denoting \( S(j) \) the second moment,

\[
S(j) \equiv \langle (ak)^2 \rangle = \sum_{k=1}^{k=N-1} P_j(k)(ak)^2, \tag{5}
\]
we obtain in a straightforward manner,

\[
\rho(j + 1) = S(j) - (S(j) - P_j(N)) + (1 - a)(\rho(j) - P_j(N)) + a(1 - P_j(N)), \tag{6}
\]
and therefore after cancellation of \( S(j) \)'s we get the simple recursion equation for \( \rho(j) \), namely

\[
\rho(j + 1) = a + (1 - a)\rho(j), \tag{7}
\]
with the explicit solution, quite easy to find,

\[
\rho(j) = 1 - (1 - a)^j = 1 - (1 - \frac{1}{N})^j, \tag{8}
\]
which in the limit of large \( N \), for \( j/N \) fixed, becomes simple exponential law

\[
\rho(j) \approx 1 - \exp\left(-\frac{j}{N}\right). \tag{9}
\]
We see that in the limit of sufficiently large \( N \), for \( j/N \) fixed, we have the universal scaling of the relative measure of chaotic region \( \rho \), normalized to unity, such that \( \rho(j) \to 1 \), when \( j \to \infty \), as a function of the scaled discrete time, namely \( j/N \). We shall show and see below, that this law is obeyed by
a surprising variety of deterministic dynamical systems.

Our random model is a probabilistic (statistical) model and therefore we can calculate all moments of $P_j(k)$, systematically, using the same trick as above: multiply the recursion relation (3) by $(k+1)^2/N^2$ on both sides, sum it up from $k = 0$ to $k = N - 1$ on both sides, and uncover the recursion relation for the second moment $S(j)$, namely

$$S(j + 1) = \frac{1}{N^2} + \left(\frac{2}{N} - \frac{1}{N^2}\right)\rho(j) + \left(1 - \frac{2}{N}\right)S(j), \quad (10)$$

and by using the exact result for $\rho(j)$ from equation (8) we have

$$S(j + 1) = 2a - a(2-a)(1-a)^j + (1 - 2a)S(j), \quad a \equiv 1/N. \quad (11)$$

This equation can be solved either by standard technique or by using the definition of $S(j)$, equation (5), to yield the explicit result

$$S(j) = 1 - (2-a)(1-a)^j + (1-a)(1-2a)^j, \quad a \equiv 1/N, \quad (12)$$

so that the predicted dispersion $\sigma^2(j)$ according to our model is exactly

$$\sigma^2(j) = S(j) - \rho^2(j) = a(1-a)^j + (1-a)(1-2a)^j - (1-a)^2j, \quad a \equiv 1/N. \quad (13)$$

In the asymptotic limit of sufficiently large number of cells $N = 1/a \to \infty$, but keeping $j/N$ fixed, we find the simple exponential laws:

$$\rho(j) \approx 1 - \exp(-j/N), \quad S(j) \approx [1 - \exp(-j/N)]^2 \approx \rho^2(j), \quad (14)$$

and therefore

$$\sigma^2(j) \approx N^{-1}[\exp(-j/N) - \exp(-2j/N)] \to 0. \quad (15)$$

Now we show the explicit and exact result for $P_j(k)$, just for the sake of completeness. In fact the quantity we seek is the subject of the classical
problem from combinatorial analysis, treated e.g. in (Vinogradov 1979, Vol.2, p.973, Riordan 1978, p.48, Table 2, Graham, Knuth and Patashnik 1994): The question is how many possibilities are there to distribute \( j \) different things into \( N \) different cells under the condition that \( N - k \) cells are empty (i.e. precisely \( k \) cells are occupied): The answer is well known, namely in the literature denoted by \( C_{Nj}(N - k) \),

\[
C_{Nj}(N - k) = \binom{N}{N - k} k! S(j, k) = \frac{N!}{(N - k)!} S(j, k),
\]

where \( S(j, k) \) are the so-called Stirling numbers of the second kind (Vinogradov 1979, Riordan 1978, Graham, Knuth and Patashnik 1994)

\[
S(j, k) = \frac{1}{k!} \sum_{i=0}^{k} \binom{k}{i} i^j (-1)^{k-i},
\]

which are known to satisfy the triangular recursion relation \( S(j, k) = kS(j - 1, k) + S(j - 1, k - 1) \), where \( S(0, 0) = 1, \ S(j, 0) = 0, \ S(0, k) = 0 \ (j, k) > 0 \). Of course, having the \( N \) cells and \( j \) things, like in our random model, the total number of possibilities to distribute \( j \) things (balls) into \( N \) cells is just \( N^j \), and therefore we have the final and complete explicit solution to the random model, namely

\[
P_j(k) = \frac{C_{Nj}(N - k)}{N^j} = \frac{N!S(j, k)}{(N - k)!N^j}.
\]

Now we proceed by analyzing specific dynamical systems from the point of view of the statistical theory presented in our random model, to see to what extent we find agreement in real systems. The really big surprise is that the behaviour was found in excellent or even perfect agreement with theory in a large variety of deterministic dynamical systems, sufficiently far from a pronounced KAM-regime, by which we mean either close to ergodic (big \( \rho_2(j = \infty) \approx 1 \)), or strongly chaotic (big Lyapunov exponent but not necessarily very large \( \rho_2(j = \infty) \)).

We have investigated the plots \( \rho(j) \) versus \( j/N \) for the following systems: (a) the 2-D billiard (Robnik 1983) at \( \lambda = 0.375 \), (b) the 3-D billiard (Prosen
1997, def. geom.: $a = -1/5, b = -12/5$), (c) the hydrogen atom in strong magnetic field (DKP = diamagnetic Kepler problem) with the *scaled energy* $\epsilon = -0.05$ (see e.g. Hasegawa, Robnik and Wunner 1989), (d) the Hénon-Heiles system at the escape (dissociation) energy $E = 1/6$ (see Hénon and Heiles 1964), (e) the standard map (Chirikov 1979) with $k = 3$, (f) the standard map (Chirikov 1979) with $k = 400$, and (g) for the logistic map at $\lambda = 4$ (the ergodic tent map).

In case of smooth systems (c) and (d) we have used special symplectic integration routines, devised by Yoshida (1990). This enabled a fast and extremely accurate calculations, allowing us to compute about the order of magnitude $10^5$ iterations on the SOS.

The agreement for all systems was perfect (deviations much smaller than 1%), except in (d) and (e), where the deviations fluctuated around up to 1%. Therefore we do not show these plots, since all curves practically overlap with the theoretical curve (8) and (9) within the graphical resolution. The small deviations stem from the fact that the Lyapunov coefficients are still not big enough, and also that there might be significant episodes of transient behaviour in the relationship of $\rho(j)$ with respect to the discrete time $j/N$. Such transient episodes are typically caused by the sticky objects in the phase space, e.g. by cantori, where the classical orbit spends long time before resuming the chaotic random filling of the remaining empty cells. They are very well manifested in systems with more pronounced KAM structure, like e.g. the 2-D billiard ($\lambda = 0.15$) or 3-D billiard (for sufficiently small $a$ and $b$, such as $a = -0.1, b = 0$). In order to describe such systematic effects in a statistical way we have developed a *multicomponent random model*, where orbital transitions inside each component are random as in our *random model*, however, they might jump (rarely) from one into another component. Some of the dynamical features are well described by such a model, whose detailed description will be published in a separate paper (Robnik, Prosen and Dobnikar 1997).

In cases (a) - (c) the agreement is so good, quite surprisingly, that it is necessary to magnify the scale so that the details of deviations become clearly visible. This is done in figures 1(a-c) for the systems, respectively. We plot the fluctuation (difference) $\rho_{\text{numerical}}(j) - \rho_{\text{theory}}(j)$ (the noisy curves) to be compared with the theoretically expected standard deviation $\sigma(j) =$
\[ \pm \sqrt{S(j) - \rho^2(j)} \] (smooth curves), again as a function of the scaled discrete time \( j/N \). We do this in each of the plots for one initial condition and for the average over 50 randomly (uniformly over the chaotic component) chosen initial conditions which suppress the dispersion by a factor of 50, of course, and the standard deviation by \( \sqrt{50} \).

The conclusion in inspecting these plots is that the 2-D billiard perfectly obeys the law of our random model, whilst for the hydrogen atom in a strong magnetic field and the 3-D billiard we uncover systematic deviations from the theory for sufficiently large scaled discrete times \( j/N \): the deviations are orders of magnitude bigger than the prediction of our random model for the DKP, but somewhat smaller in the 3-D billiard. It should be noted that the deviations are almost strictly negative, reflecting the fact that the physical orbits like to stick to already occupied cells (existence of sticky objects in the phase space).

It is interesting to look at the results for random number generators. Cells are "randomly" chosen, using different random number generator algorithms. One such algorithm was devised by Finocchiaro et al (1993) in the context of nuclear physics. The agreement was perfect and so we do not show the fluctuations plots.

Also, we have checked and tested some well known algorithms for random number generators, such as ran0, ran1, ran2 and ran3 devised and described in (Press et al 1986, ch. 7, and the references therein). The results are shown in figure 2. As we see ran0 and ran3 are in excellent agreement with our random model, whilst for ran1 and ran2 random generators the deviations become clearly very large. Thus, for example, our dynamical deterministic 2-D billiard systems, or the logistic map, or the standard map at \( k = 400 \), are in fact better random number generators than some of the most familiar random number generators used in the computers.

Finally, we have looked at the irrational triangle (the angles are \( \alpha = (\sqrt{5} - 1)\pi/4 \), \( \beta = (\sqrt{2} - 1)\pi/2 \)) as one ergodic system with strictly zero Lyapunov exponents (Sinai 1976). Even there the agreement with our random model is surprisingly good on the largest scale (figure 3), while the fluctuation diagramme exhibits large deviations, again negative, showing that the real
billiard orbits like to stay in the already occupied regions (sticky objects in phase space).

In conclusion, we have developed the random model of stochastic diffusion of dynamical systems with invariant measure on their Surfaces of Section, which is supposed and confirmed to apply very well in strongly chaotic systems (for which the Lyapunov coefficients on the chaotic component are sufficiently large). We have discovered and explained the universal scaling behaviour of the normalized chaotic measure $\rho$ as a function of the scaled discrete time $j/N$, where $N$ is the number of cells: namely, in the limit of sufficiently large $N$, for $j/N$ fixed, we have a simple exponential law $\rho(j) = 1 - \exp(-j/N)$. We also predict the higher moments, especially the dispersion given in equation (13). The model is solved completely in the sense that we have calculated the probabilities $P_j(k)$ of having exactly $k$ non-empty cells at time $j$. Therefore, one can calculate all the moments. The deviations from the predictions of the random model are qualitatively understood, but will be treated in detail together with a new, more general theory (the multicomponent model) in a separate work (Robnik, Prosen and Dobnikar 1997). The work is in a sense extension of the theory of transport in Hamiltonian systems by MacKay, Meiss and Percival (1984).

**Figure 1(a-c):** We show the plots of $\rho_{\text{numerical}}(j) - \rho_{\text{theory}}(j)$ versus the scaled discrete time $j/N$. The outer noisy curve is the numerical result for a chaotic orbit with a certain representative initial condition, whilst the inner one is the average over fifty evenly distributed initial conditions. We also show the $\pm \sigma(j)$ standard deviation, as predicted theoretically in equation (13). It is clearly seen that for the 2-D billiard in (a) the agreement is almost perfect, in the sense that the fluctuations are within the predicted range, whilst for the 3-D billiard in (b) we see systematic deviations, obviously caused by some perhaps unexpected long time correlations. Such correlations are even stronger in case of the hydrogen atom in a strong magnetic field, shown in (c). In all cases the deviations are predominantly negative: the orbit tries to stick to some of the already occupied cells.

**Figure 2:** We show the results for the random number generators, compared by the theoretical $\pm \sigma(j)$ curves according to equation (13) (Press et al 1986): for ran0 and ran3 the agreement is excellent, while for ran1 and ran2 the deviations are so big, that they are actually not random: they seem to repel from the occupied cells.

**Figure 3:** We show the global plot, $\rho_{\text{numerical}}(j)$ (full line) and $\rho_{\text{theory}}(j)$ (dashed), for the irrational triangle, where the agreement is surprisingly good, in spite of strictly vanishing Lyapunov exponents. In the fluctuations diagramme we plot $\rho_{\text{numerical}}(j) - \rho_{\text{theory}}(j)$ versus $j/N$, together with the $\pm \sigma$, where we see the same trend to negative deviations due to the sticky objects in the phase space.
