Effect of the chemical vapor deposition condition on the electrochemically catalytic efficiency for hydrogen evolution reaction in MoS$_2$ nanoparticles

Quyen Le Do, Duc Anh Nguyen*

ABSTRACT
Introduction: Using the metal organic chemical vapor deposition (MOCVD) method, we have synthesized the MoS$_2$ nanoparticles on graphite foil substrates employed as the electrochemical working electrodes with highly efficient electrocatalysis for hydrogen evolution reaction (HER). Methods: The morphological and structural properties of the as-grown MoS$_2$ materials were demonstrated by field emission scanning electron microscope (FESEM) and Raman spectrocopies, while their elemental components were investigated by X-ray photoelectron spectroscopy (XPS). Results: The optimum growth time was acquired to be 11 hours. Thereby such obtained electrode exhibited the maximum HER activity with onset over the potential of 220 mV versus reversible hydrogen electrode (RHE), and the Tafel slope of 66 mV per decade (mV/dec). Conclusion: Our results suggest a good technique for the research of high-efficient HER electrocatalyst based on atomic-thickness layered materials. Key words: MoS$_2$ nanoparticles, metal-organic chemical vapor deposition, hydrogen evolution reaction

INTRODUCTION
Hydrogen gas, an excellent source of clean energy, has been demonstrated as an ideal replacement for hydrocarbon-based and fossil fuels. Hydrogen gas can be conveniently yielded from the electrochemical water splitting reaction. Using this approach, the hydrogen evolution reaction (HER) that happens on a cathode surface can be accelerated by loading an electrocatalyst on it. However, the best electrocatalysts for HER are Pt and its relation noble metals, which has substantially limited their commercial massive production. Thus, developing low-cost electrocatalysts that possess strong stable and HER performance to be close to Pt-based catalysts is ultimately desirable. So far, nanostructures of molybdenum disulfide (MoS$_2$) have been proven promising candidates for excellent catalytic activity. Using DFT calculation, J. K. Nørskov's group first reported that hydrogen adsorption Gibbs free energy of edge sites of MoS$_2$ is close to zero ($\Delta G_{\text{HR}} \sim 0$ eV), suggesting MoS$_2$ probably as a great HER catalyst. The experimental measurements then assured this prediction of HER performance of MoS$_2$ nanoparticles on graphite, and Au(111) substrates. Subsequently, numerous reports have focused on maximizing the exposed active-edge-sites, arming to enhance the HER activity of MoS$_2$. These efforts can be the growth of vertical nanoflakes, nanobelts, mesoporous, or nanoparticles. On the other hand, due to low intrinsic conductivity in MoS$_2$, one can reduce the number of layers to minimum the charge transfer resistance between the exposure surface at the outmost layer and the electrode. In this regard, a small number of layers was demonstrated as another important expect for highly catalytic HER performance in MoS$_2$ nanostructure. Generally, MoS$_2$ nanostructure with a small number of layers (around 2–4 layers) might be a great alternative of noble-metal-based HER electrocatalysts. However, synthesis a large scale of few-layer MoS$_2$ nanostructure directly on conductive substantial has been still difficult.

Here, we used the MOCVD technique to grow MoS$_2$ nanoparticles directly on conductive graphite, which was applied for HER electrochemical working electrode. This work focused on the dependence of HER performance on the MOCVD growing condition, particularly the growth time. We found the sample grown in 11h to exhibit the highest HER activity with the smallest onset overpotential of 250 mV/dec, and the Tafel slope of 66 mV/dec.

Synthesis of MoS$_2$ nanoparticles

MoS$_2$ nanoparticles were synthesized via MOCVD, as schematically illustrated in Figure 1. Briefly, the experiment was taken place in a sealed 1-inch diameter quartz tube, and then graphite foil electrodes were placed at the center of the heated zone. The metal-organic compound of molybdenum hexacarbonyl (MHC, C$_6$MoO$_6$) and diethyl sulfide (DES, C$_4$H$_{10}$S) have high equilibrium vapor pressure were used as the gaseous precursors. Firstly, the base vacuum (~1 mtorr) was established in the chamber by a rotary pump. At the same time, the temperature of MHC and DES bearer was adapted at 25\(^\circ\)C and 60\(^\circ\)C, respectively. Then, a flow of 1 standard cubic centimeter per minute (sccm) of Ar gas was injected into DES bearer to dilution and thus facilitated the DES vapor flow. The temperature of the carrier line was fixed at 50 \(^\circ\)C, and that of the reaction zone was 550\(^\circ\)C. A mixture of 30 sccm of Ar and 5 sccm of H$_2$ was continuously flowed into the reaction chamber during all growing processes to maintain the working pressure to be 60 torrs. Subsequently, the reaction process was started by introducing 1 sccm mix of (Ar + DES) and open soft valve of the MHC holder. For a comparative investigation of HER reactivity, MoS$_2$ samples with various deposition times of 7, 9, 11, 13 h by a similar deposition condition.

Characterization

The morphology of MoS$_2$ samples was characterized by field-emission scanning electron microscopy (JSM-6500F, JEOL). The lattice vibrational properties were investigated by micro-Raman spectroscopy using a 473 nm excitation source under ambient conditions. The X-ray photoelectron spectroscopy (XPS) measurements were carried out using a Theta Prove AR-XPS System (Thermo Fisher Scientific).

RESULTS

The morphology of MoS$_2$ nanoparticles was observed by FESEM images, as shown in Figure 2. As shown in Figure 2a and b, the 6h grown sample is similar to the blank substrate, indicating that before 6h, the MoS$_2$ has not been formed in the substrate. When the growth time reaches 7h (Figure 2c), tiny particles appear with the size of 50-100 nm. According to Figure 2d-f, the density of the nanoparticles increased with the growth time, while the size of particles seems to be not changed. Figure 3 shows the Raman spectra of the obtained MoS$_2$ samples. As shown in Figure 3a, two peaks located at 378.2 and 401.5 are attributed to the two typical active Raman scattering mode of E$^1_{2g}$ and A$_{1g}$ vibrational modes in 2H phase of MoS$_2$, in which the
Figure 2: Morphological analysis. FESEM images of bare graphite foil (a), and MoS$_2$ nanoparticles (b-f) synthesized for 6, 7, 9, 11, 13 h. The scale bar is 1 μm.

Figure 3: Raman spectra of MoS$_2$ nanoparticles on graphite substrate (a). The zoom-in of the Raman spectra of samples grown in 7 h to 13 h.

The first one (E$_{2g}^1$) is attributed to the in-plane vibration of Mo-S bond, while the other one (A$_{1g}$) is corresponding to the out-of-plane vibration of S atoms. Moreover, the frequency separation between these two peaks of 23.5 cm$^{-1}$ suggested that the number of layers was between 3 and 4 layers. Although the growth time is much different (alternating between 7 h to 11 h), the number of layers of samples does not change, reflected by the non-shift in the Raman peaks position (Figure 3b).

The X-ray photoelectron spectroscopy (see Figure 4a-b) was constructed to study the elemental bonding states of as-grown MoS$_2$ nanoparticles. Figure 4a illustrated the high-resolution of XPS spectra in Mo 3d region. As can be seen, the two olive-fitted peaks located at 229.65 and 232.8 eV are corresponding to Mo$^{4+}$ 3d$_{5/2}$ and Mo$^{4+}$ 3d$_{3/2}$ energy levels in MoS$_2$, respectively. Besides, the two small peaks (orange fitted curves) overbed at 231.8, and 235.9 eV are ascribed to the Mo$^{6+}$ states, indicating the formation of a small amount of molybdenum oxide due to partial oxidation of MHC throughout the deposition process. Additionally, two blue fitted peaks that were detected at 162.5 and 163.7 eV (see Figure 4b) are attributed to the S$^{2-}$ 2p$_{3/2}$ and S$^{2-}$ 2p$_{1/2}$ energy states in MoS$_2$, respectively. Thus, all these data confirmed the chemical elemental composition of the fabricated materials.
The HER performance was firstly examined by the linear sweep voltammetry (i.e., polarization curves), as illustrated in Figure 5a. As can be seen, there was a considerable enhance of HER activity as the CVD growth time increase from 7h to 11h. The 11h sample revealed the highest performance with the onset overpotential of approximately 250 mV vs. RHE, which was considerably smaller than the 7h, 13h, and bare samples. The Tafel plots can also be used to evaluate the electrocatalytic activity for HER, in which the smaller obtained Tafel slope corresponds to the higher HER reactivity. Figure 5b exhibited the corresponding Tafel plots of the MoS$_2$ nanoparticles synthesized at different times. Even though the 9h sample exhibited a similar onset overpotential with the 11h sample, its Tafel slope of 91 mV/dec was much higher than that of the 11h sample (66 mV/dec). However, when we further expanded the deposition time until 13h, the performance experienced a degeneration with the onset overpotential and the corresponding Tafel slope enlarged to ~350 mV vs. RHE and 88 mV/dec, respectively. Generally, the MoS$_2$ nanoparticles deposited in 11h exhibited the optimum electrochemically catalytic activity for HER.

To evaluate the density of the active site of catalysts, the cyclic voltammetry (CV) plots in a non-Faradic potential range were conducted at the scan rates changing between 10 and 70 mV/s, as shown in Figure 5c. Then, the double-layer capacitance ($C_{dl}$) obtained from the linear fitting the dependance of the average current density versus scan rates (Figure 5d) was demonstrated to be proportional to the active site density.\textsuperscript{24} As can be seen, the 11h sample exhibited the maximum $C_{dl}$ of 2.21 mF/cm$^2$, which is considerably larger than that of the rest ones. Thus, although the morphology and the density of MoS$_2$ nanoparticles of 11h and 13h samples are almost similar, the former reveals a significantly higher performance than the latter. Nevertheless, these calculations of the electrochemically active surface area of catalysts were well consistent with the above polarization curves.

Finally, the stability test for the HER catalytic activity of 11h sample was investigated by the transient chronopotentiometry measurement with a working current density of -5 mA/cm$^2$, as depicted in Figure 5e. During a period of 20h, we observed no significant variation of overpotential, demonstrating great stability. In addition, the nominal modification of polarization curves before and after the durability characterization verified the superior working stability of as-obtained MoS$_2$ nanoparticles (Figure 5f).

**DISCUSSION**

As mentioned, the MoS$_2$ nanoparticles that recently have been considered as a promising candidate for highly efficient electrocatalytic for HER were fabricated. Remarkably, our MOCVD method supported a direct growth of MoS$_2$ nanoparticles on conductive graphite foil electrodes which simplified the material preparation. The electrode surficial phenomena were tested without any extra transfer process. In this way, it also naturally avoided the electrical loss contacts for the electrochemical measurements. For catalytic HER activity, the electrochemically active sites play an essential role. Frequently, the active sites locate at the edge-sites rather than at the basal plane. As a result,
ragged particles in nanoscale size are more favorable than a uniform continuous film. In addition to the morphological aspects, the thickness of MoS$_2$ material is another essential factor affecting total performance. The layer number ranging from 3 to 4 was demonstrated as the best option for HER reactivity. Interestingly, the fabricated MoS$_2$ particles in this work well matched with above requirements. In this study, under the same reaction temperature, carrier gas concentration, and precursors’ flow rate, the morphology (i.e. size and layer number) of MoS$_2$ nanoparticles was similar; therefore, the catalytic activities essentially only depended on the density of particles. Meanwhile, the growth time led to the change of particle density. Thus, for the samples grown from 7 to 11h, a considerable enhancement in the electrocatalytic activity can be easily understood as extending the density of MoS$_2$ nanoparticles. However, we assert that a further extending growth time ($\geq 13$h) should not be employed to acquire the optimum performance. We attributed the best HER performance of 11h samples to the maximum of active
sites through extra growth time to the inert S-edge. This mechanism should be further confirmed in the following research topic. Finally, although the obtained performance of the present MoS$_2$ sample was relatively better than that of some previous MoS$_2$ based materials, it has been still far from that of Pt-based catalysts (Tafel slope -30 mV/dec)\textsuperscript{27}. Therefore, some additional works are required to improve current results further. We suggest that the efficiency of MoS$_2$ nanoparticles can be further enhanced by activating the basal plane of MoS$_2$ nanoparticles by further applying surficial treatment routes, such as doping, engineering S-vacancies defect positions or hybridization with a high-surface-area substrate.

**CONCLUSION**

We have reported the method, namely MOCVD, to synthesize MoS$_2$ nanoparticles applying for the HER electrocatalysis. We found that the deposition time considerably affected the HER efficiency in which the electrochemically active sites density played an essential factor. Particularly, the 11h deposited MoS$_2$ sample showed the highest active site density, thereby the best HER performance with onset overpotential of 250 mV vs. RHE, and the Tafel slope of 66 mV/dec. Thus, this search may provide a straightforward and convenient route to acquire a good replacement to the Pt-based electrocatalysts.
