Abstract

Large-scale constructions of urbanization increase the impervious areas of city, leading to the urban hydrological effects such as urban waterlogging and rainwater runoff pollution. To this end, China proposed to adopt the measure to build sponge cities. However, the existing green soil cannot meet the comprehensive needs of sponge city. In order to quickly evaluate the comprehensive performance of the soil in sponge city, a comprehensive evaluation criterion was designed, which is related to the characteristics of greening soil permeability, porosity, pH, salinity and fertility. Based on the criterion, a new type of composite green soil was obtained with the silt soil: medium sand: sawdust ratio of 72.5\%: 20\%: 7.5\%. Finally, compared with the existing soil, the new green soil not only meets the comprehensive performance requirements of the green soil's fertility, pH, permeability and other factors, but also has higher permeability and water retention. It was proved that the new green soil has apparent advantages in the control of rainwater.

Keywords: Compound green soil, Comprehensive performance, Evaluation criterion, Improvement, Sponge city
1. Introduction

After decades of development, the urbanization construction in China has made great achievements, and megacities such as Shanghai are leading the country and developing rapidly [1, 2]. However, influenced by the increase in large-scale urbanization construction, a large increase in impervious areas has led to significant urban hydrological effects, including urban waterlogging and rainwater runoff pollution [3-5]. To solve a series of urban problems caused by the urbanization process, China proposed to build sponge city with natural accumulation, natural penetration and natural purification based on LID technology [6]. The sponge city mainly realizes the benign hydrological cycle of the city by various technical means such as "seepage, stagnation, storage, purification, use and drainage", thereby improving the ability of penetration, storage, purification, utilization and discharge of runoff rainwater [7]. As essential sponge facilities in the construction of sponge cities, green roofs, rain gardens, sunken green spaces, artificial soil infiltration, etc. have high requirements on soil [8-13]. Therefore, the green soil in the sponge city plays a particularly important role in its construction.

The green soil in the sponge city not only needs to meet the basic needs of greening plants, but also to make the rain quickly infiltrate when the heavy rain comes. Besides, the capacity of soil should hold a certain amount of water in a short time to stagger the peak runoff time and improve the management and control of rainwater. Therefore, the soil should have high permeability, high water holding capacity, high aeration porosity and high fertility [14, 15]. However, with the rapid development of various municipal and civil engineering constructions, urban green soil at the stage has experienced serious compaction and degradation. It features low
permeability, poor structural morphology, high levels of foreign matter and low organic matter content [16-20]. These features are conducive to neither the infiltration and drainage of urban rainwater, nor the growth of green plant. Moreover, the current greening soil cannot fully exert the benefits of the sponge city's facilities for rainwater management. Therefore, to enhance the efficiency of sponge cities, it is urgent to improve the current urban green soil.

At present, many scholars have conducted extensive and in-depth investigations and studies on the improvement of green soil in sponge cities. For permeability, Wei et al. (2010) [21] pointed out that edible fungus residue can improve soil and increase soil permeability. Besides, Tian et al. (2011) [22] verified this conclusion experimentally. Wei et al. (2011) [23] used soil, medium sand, hot metal slag, and sawdust to improve the soil infiltration rate. Besides, Zhu et al. (2013) [24] added 5% humus soil and 15-35% sand to the red loam soil, which has significantly improved soil permeability. For soil fertility, Shen et al. (2011) [25] studied the improvement of soil fertility by using waste diatomite through field leaching. It was found that waste diatomite had a significant effect on improving soil fertility and its reasonable amount was 5.2-6.0% of soil content. For water holding capacity, Chu et al. (2017) [26] pointed out that the ratio of soil to sand affects the water holding capacity. When the ratio of sand to the soil is 1: 2, 1: 1, and 2: 1, the total amount of soil water storage decreases in turn. For removing contaminants, Jing et al. (2019) [27] designed a high NH$_3$-N removal urban sponge for application in red soils, which also has high permeability.

The researches mentioned above have laid a solid foundation for the improvement of green soil in sponge cities. However, most of them focused on one or two aspects of research,
failing to comprehensively consider the physical and chemical parameters of the soil so that the researches are more one-sided. The requirements of the sponge city for soil include various factors such as high permeability, high water holding capacity, suitable pH and high fertility. Therefore, a new type of greening soil of the sponge city should be designed, which can meet the all requirements of soil fertility, permeability, pH, and water holding capacity. This new type of soil could be prepared by adding sand and improved materials to the silt soil in a certain proportion.

This study aims to design an evaluation criterion that can quickly evaluate the comprehensive performance of green soil. Besides, it also aims to design a new type of composite green soil with high permeability, high water holding capacity and high fertility. Moreover, the study compared the comprehensive characteristics of the new greening soil with other existing soil to demonstrate the superiority of the new greening soil.

2. Materials and Methods

2.1. Formulation of the Evaluation Criterion

According to the relevant design requirements ("Greening Planting Soil" (CJ/T340-2016), "Garden Greening Planting Soil Quality Specification" (DG/TJ08-231-2013)), the greening soil should have the characteristics of high permeability, high water holding capacity, good aeration porosity, high fertility and suitability of plant growth. Moreover, in the process of controlling rainwater in sponge cities, the greening soil is required to have high permeability and good water holding capacity. It was proved that the water holding capacity of soil and bulk density have the
good correlation with total porosity [28-30]. Therefore, six parameters of permeation rate, total porosity, aeration porosity, pH, salt content and organic matter content were selected as soil characteristic parameters. In the case involving six parameters, in order to quickly evaluate the quality of green soil in sponge city, an evaluation criterion was established and a comprehensive quantitative index was defined. Besides, the six parameters were graded according to the numerical range and given corresponding scores.

For the evaluation criterion, firstly, according to the relevant norms or academic research conclusions, the basic limit line of each parameter was obtained, which was the pass line. Secondly, the value corresponding to the pass line was changed by about 10% or take an integer to change the grading level accordingly, so as to complete the division of the evaluation standard system. Then, in each parameter score, 1 point is the lowest score and the highest score is 5 points. Specifically, 3 points are the lowest value that meets the relevant norms or scholars’ research conclusions, which is defined as a passing score. The result of exceeding the limit of the relevant norm or scholar’s research conclusion is 1 point, and the result of the highest degree of agreement with the relevant norm or scholar's research conclusion is 5 points.

2.1.1. Permeation rate

According to the relevant specification ("Greening Planting Soil" (CJ/T340-2016)), the penetration rate is required between $2.78 \times 10^{-6}$ m/s and $100 \times 10^{-6}$ m/s. Therefore, the result of less than $2.78 \times 10^{-6}$ m/s or more than $100 \times 10^{-6}$ m/s is 1 point. The saturated stable penetration rate of compound greening soil was set to $5.56-14 \times 10^{-6}$ m/s. The rate of $5.56 \times 10^{-6}$ m/s is twice
the required minimum value of $2.78 \times 10^{-6}$ m/s, which was increased by 10% to obtain an integer of $6 \times 10^{-6}$ m/s. Further, the penetration rate score of $5.56 - 6 \times 10^{-6}$ m/s is 3 points. In addition, the penetration rate of $14 \times 10^{-6}$ m/s has an excellent treatment rate of stormwater accumulation.

Meanwhile, considering the relationship between the penetration rate and the water holding capacity, the result of $2.78 - 5.56 \times 10^{-6}$ m/s or $14 - 100 \times 10^{-6}$ m/s divided into 2 points. Moreover, $7 \times 10^{-6}$ m/s is the conclusion that the greening soil has good penetration effect and purification effect. Therefore, the result of $6 - 7 \times 10^{-6}$ m/s is 4 points. Finally, for the better permeability, the result of $7 - 14 \times 10^{-6}$ m/s is 5 points.

2.1.2. Total porosity

According to the Eq. (1), the total porosity was calculated as 51% when the bulk density of the soil was $1.3 \text{ g/cm}^3$ (average bulk density of natural soil); 49% when the $1.35 \text{ g/cm}^3$ (hinders plant growth when greater than $1.35 \text{ g/cm}^3$). Besides, when the total porosity is more than 50%, it is suitable for the green plant, and 50%-56% is the best. However, when it is more than 60%, it is not suitable as green soil [31]. Then, 50% was decreased by 10% to get the critical line of 45%, so the result of less than 45% or more than 60% is 1 point and 49-50% result is 3 points. Moreover, the result of 45-49% or 56-60% is given as 2 points. In the end, the result of 50-51% is 4 points, and 51-56% is 5 points.

$$n \text{ }(\%) = (1 - \rho_b / \rho_s) \times 100\% \quad (1)$$

where $\rho_s$ is the Soil particle density, and it usually takes the value of $2.65 \text{ g/cm}^3$. 
2.1.3. Aeration porosity

It is great when the aeration porosity is more than 10%, and 15-20% is better [16, 31]. Moreover, according to relevant specifications ("Garden Greening Planting Soil Quality Specification" (DG/TJ08-231-2013)), 8%, 10% and 15% are the requirements for aeration porosity under different planting conditions. Therefore, the result of less than 8% or more than 20% is 1 point. Taking into account the correlation between water holding capacity and aeration porosity [32], a 10% reduction in aeration porosity of 20% could give a limit line of 18%. Then, the result of 8-10% or 18-20% is 2 points. In addition, increasing 10% by 10% results in a limit line of 11%. Thus, the result of 10-11% is 3 points. Finally, the result is 11-15% for 4 points and 15-18% for 5 points.

2.1.4. pH

According to the different test methods in the specification ("Greening Planting Soil" (CJ/T340-2016)), it is required between 5.0 and 8.3 in the water-soil ratio method and 5.0-8.0 in the saturation method. Besides, the score of pH also needs to be based on the characteristics of the plant being planted. In the absence of specific planting conditions, this system does not consider the range of 4 points and 5 points. Finally, according to the general range, the result of less than 5 or more than 8.3 is 1 point; the result of 5-5.5 or 8-8.3 is 2 points and 5.5-8.0 is 3 points.

2.1.5. Salt content
It is not conducive to plant growth when the soil salt content exceeds 1,000 mg/kg. Besides, according to the norm ("Geotechnical Engineering Investigation Code" (GB50021-2001)), it would have a negative impact on plant growth when the soluble salt content is between 3000 mg/kg and 10,000 mg/kg. Therefore, the result is 1 point for more than 10,000 mg/kg; 2 points for 1,000-10,000 mg/kg. Then, 1,000 mg/kg was reduced by 10% and 20% in turn to get 900 mg/kg and 800 mg/kg, respectively. Finally, the result of 900-1,000 mg/kg is 3 points; 800-900 mg/kg is 4 points, and the result of less than 800 mg/kg is 5 points.

2.1.6. Organic matter content

According to the specification ("Greening Planting Soil" (CJ/T340-2016)), the basic organic matter content of the greening soil is 12-80 g/kg. Moreover, considering the fertility of the greening soil, it is required that the organic matter content should be 20-80 g/kg. The organic matter content of 25 g/kg could meet the basic requirements given in planting situations. Organic matter content at 35-80 g/kg meets the various planting conditions specified in the specifications, so the highest score. Therefore, the result of less than 12 g/kg or more than 80 g/kg is 1 point; 12-20 g/kg is 2 points; 20-25 g/kg is 3 points; 25-35 g/kg is 4 points, and 35-80 g/kg is 5 points.

2.1.7. The evaluation criterion

According to the results of the above parameter standards, the comprehensive performance evaluation criterion of green soil was finally obtained, as shown in Table 1. Based on the evaluation criterion, the comprehensive score $\beta$ of greening soil could be calculated. Then, $\beta$ is
the sum of 6 sub-items, and each sub-item score has the same weight. The larger the value, the better the quality of the greening soil. If any two or more of the 6 sub-items are less than 3 points, it is determined that the sample does not meet the relevant engineering and technical requirements.

Table 1. Evaluation Criterion for Comprehensive Performance of Green Soil

| Item                      | Score Range          |
|---------------------------|----------------------|
| Penetration rate          | < 2.78 or > 100      |
| (×10^{-6} m/s)            | 2.78-5.56 or 14-100 |
|                           | 5.56-6               |
|                           | 6-7                  |
|                           | 7-14                 |
| Total porosity ( % )      | < 45 or > 60         |
|                           | 45-49 or 56-60       |
|                           | 49-50                |
|                           | 50-51                |
|                           | 51-56                |
| Aeration porosity ( % )   | < 8 or > 20          |
|                           | 8-10 or 18-20        |
|                           | 10-11                |
|                           | 11-15                |
|                           | 15-18                |
| pH                        | < 5 or > 8.3         |
|                           | 5-5.5 or 8.0-8.3     |
|                           | 5.5-8.0              |
|                           | *                    |
|                           | *                    |
| Salt content ( mg/kg )    | > 10,000             |
|                           | 1000-10,000          |
|                           | 900-1,000            |
|                           | 800-900              |
|                           | < 800                |
| Organic matter content ( g/kg ) | < 12 or > 80        |
|                           | 12-20                |
|                           | 20-25                |
|                           | 25-35                |
|                           | 35-80                |

* "-" means the corresponding grade score needs to be given according to the specific plants.

The value standard of this system refers to the Scholar's research conclusions and the urban construction standard promulgated by the State Housing and Urban-rural Construction Bureau, and their application scope is very wide. Meanwhile, the problems of serious compaction, poor fertility, and low permeability of urban green soils are widespread in most parts of China. Therefore, the evaluation criterion is applicable in most areas of China.
2.2. Silt Soil

Silt soil was obtained from the Shanghai green belt through a series of processes such as air drying, impurity removal and screening. Finally, the air-dried soil with a particle size of less than 2 mm was obtained. The particle gradation is shown in Table S1.

2.3. Medium Sand

Medium sand is the air-dried sand with the particle size of less than 2 mm, which was obtained through a series of processes such as drying, impurity removal, and screening after being retrieved from the river sand. Its particle gradation is shown in Table S2.

2.4. Improved Materials

For improved materials, diatomite has strong water absorption, stable physical and chemical properties. The use of dynamite could improve the function of water and fertilizer retention in green soil [33, 34]. Moreover, blast furnace slag has strong water absorption and decontamination ability. Adding blast furnace slag to the soil could significantly improve the permeability of soil [35]. Sawdust could not only improve the structure of soil, but also could provide biological nutrients. It was proved that sawdust could improve soil permeability and maintain green soil moisture [36, 37]. The mushroom residue is rich in various nutrients and could be applied to the soil after high-temperature compost treatment to improve the soil structure [38, 39].
Therefore, this study used four added materials: diatomite, blast furnace slag, sawdust and mushroom residue. The diatomite and the blast furnace slag are powdered. Meanwhile, the sawdust is camphor wood sawdust, accounting for 79.9% of the sawdust whose particle size is less than 1 mm and 20.1% of the sawdust whose particle size is 1-2 mm. The particle size of the selected mushroom residue is less than 2 mm, as shown in Fig. S1.

2.5. Experimental Scheme

(1) The sand and silt soil uniformly were stirred according to 1: 4 [22].

(2) The mixed soil was divided into four major groups A, B, C, and D. Then, the added materials respectively are diatomite, blast furnace slag, sawdust and mushroom residue. Each major group was set with 4 improved material addition ratios. Besides, each ratio is a small group, and each small group is set with 4 samples. Namely, there were a total of 4 major groups, 16 small groups and 64 samples, as shown in Table 2.

| Group | Soil (%) | Sand (%) | Improved material (%) |
|-------|----------|----------|-----------------------|
| A1    | 77.5     | 20       | 2.5                   |
| A2    | 75       | 20       | 5                     |
| A3    | 72.5     | 20       | 7.5                   |
| A4    | 70       | 20       | 10                    |
| B1    | 77.5     | 20       | 2.5                   |
| B2    | 75       | 20       | 5                     |
| B3    | 72.5     | 20       | 7.5                   |

| Group | Soil (%) | Sand (%) | Improved material (%) |
|-------|----------|----------|-----------------------|
| C1    | 77.5     | 20       | 2.5                   |
| C2    | 75       | 20       | 5                     |
| C3    | 72.5     | 20       | 7.5                   |
| C4    | 70       | 20       | 10                    |
| D1    | 77.5     | 20       | 2.5                   |
| D2    | 75       | 20       | 5                     |
| D3    | 72.5     | 20       | 7.5                   |
(3) The characteristic parameters of each small group were measured: stable permeation rate, total porosity, aeration porosity, pH, salt content and organic matter content.

Firstly, according to the specification ("Determination of Forest Soil Permeability" (GB/T 7838-1987)), the stable permeation rate was measured by the cutting ring method, and the soil samples were fully saturated and then tested. Then, according to the Eq. (1), the total porosity could be calculated. Besides, for the aeration porosity, according to specification (Forest soil moisture-determination of physical properties (LY/T 1215-1999)), it could be by Eq. (2). Among them, the maximum water holding capacity and field water holding capacity could be obtained through immersion saturation test and drainage test.

\[ n_t(\%) = (w_z - w_f) \times \rho_p / \rho_w \times 0.1 \]  

(2)

where \( w_z \) is maximum water holding capacity; \( w_f \) is field water holding capacity; and \( \rho_w \) is water density.

The pH and salt content were directly measured by the pH meter and TDS meter provided by the soil nutrient quick tester (HM-TYA). In addition, the organic matter content was measured by the soil nutrient quick tester (HM-TYA) through the principle of colorimetry.

(4) The comprehensive score \( \beta \) of green soil in each group were calculated. Then, the optimal group was determined according to the \( \beta \), and then the best improved material was determined.

(5) The medium sand addition ratio of the optimal group was changed. From the subsequent test results in Table 4, the C2 and C3 groups were the optimal groups. Therefore, the medium sand
addition ratios are respectively set to 15%, 20% and 25%. Finally, the two major groups called E and F were set up, each major group has three small groups, and each small group has four samples. Namely, a total of two major groups, six small groups and 24 samples were set up, as shown in Table 3.

Table 3. Test Proportion Setting of Group E and F

| Group | Soil (%) | Sand (%) | Sawdust (%) |
|-------|----------|----------|-------------|
| E1    | 80       | 15       | 5           |
| E2    | 75       | 20       | 5           |
| E3    | 70       | 25       | 5           |
| F1    | 77.5     | 15       | 7.5         |
| F2    | 72.5     | 20       | 7.5         |
| F3    | 67.5     | 25       | 7.5         |

(6) The characteristic parameters of each group were measured: stable permeation rate, total porosity, aeration porosity, pH, salt content and organic matter content. The measurement methods were the same as that of the third step mentioned above.

(7) The comprehensive score $\beta$ of green soil in each group were calculated, and the optimal group was determined.

3. Results and Discussion

3.1. The Comprehensive Performance of the Four Groups A, B, C and D

The grouping statistics of the six parameters are shown in Fig. 1.
Fig. 1. Test data of various parameters in groups A, B, C and D.
According to Fig. 1, for the stable penetration rate and total porosity, the improvement in group C is obvious, reflecting that the improved material in group C has the significant improvement in the stable penetration rate and total porosity. Then, for aeration porosity, group B has the larger values. However, the values of each group don't change significantly with the increase in the adding ratio, which reflects these four improved materials don't significantly improve the aeration porosity. Besides, for pH, the values of these four groups are not much different and there is no obvious change with the increase of the addition ratio. Moreover, the values of salt content of C and D groups are larger than A and B groups. Finally, group C has the obvious advantage in organic matter content, which reflects the improved material in group C has higher organic content.

According to the test data, the comprehensive score $\beta$ of greening soil for each group of test samples were calculated in this section, as shown in Table 4.

| Group | v | n | $n_r$ | pH | $w_s$ | $w_o$ | $\beta$ | ? |
|-------|---|---|------|----|------|------|-------|---|
| A1    | 2 | 3 | 4    | 5  | 1    | 18   | ×     |   |
| A2    | 2 | 3 | 4    | 5  | 1    | 18   | ×     |   |
| A3    | 1 | 4 | 2    | 3  | 5    | 1    | 16    | × |
| A4    | 1 | 4 | 4    | 3  | 5    | 1    | 18    | × |
| B1    | 3 | 2 | 4    | 2  | 5    | 1    | 17    | × |
| B2    | 4 | 2 | 4    | 2  | 5    | 2    | 19    | × |
| B3    | 2 | 2 | 4    | 1  | 5    | 1    | 15    | × |

| D4    | 4 | 4 | 2    | 3  | 5    | 5    | 23    | √ |

Where “×” means unqualified, and “√” means qualified.
According to the calculation results, the two major groups A and B using diatomite and blast furnace slag improved materials were unqualified. The two major groups C and D using sawdust and mushroom residue were qualified. Moreover, about the score of each item, all items in the C2 and C3 groups have a score of 3 or more, and $\beta$ values were 26 and 27, respectively. The improvement effect of these two groups was the best. Finally, the three added materials of diatomite, blast furnace slag and mushroom residue were discarded. Meanwhile, the C2 and C3 groups were determined to be the optimal groups.

Therefore, according to the evaluation criterion, the two unqualified improved materials, diatomite and blast furnace slag were discarded, and mushroom residue and sawdust were qualified improved materials. At the same time, sawdust is the better improved material than mushroom residue as improved materials based on the scores of each item. Moreover, two better addition ratios of sawdust were obtained. It effectively demonstrated the superiority of the evaluation criterion that it could quickly evaluate the comprehensive performance of green soil. However, the comprehensive performance of green soil was neglected in previous researches, and only one or two factors were considered.

3.2. Comprehensive Performance Test of Groups E and F

The grouping statistics of each characteristic parameter of groups E and F are shown in Fig. 2.
**Fig. 2.** Grouping statistics of each characteristic parameter of groups E and F.
It could be seen from the Fig.2 that for the stable penetration rate and total porosity, the values of the addition ratio of 7% are larger than the values of 5%, which again reflects sawdust could effectively improve the penetration rate and total porosity. Besides, for the aeration porosity and pH, the values of 7% adding ratio are not much different from the values of 5%, which reflects sawdust has little effect on aeration porosity and pH of soil. Moreover, for salt content, the values of adding ratio of 5% are larger than the values of 7%. That's because the soil samples with the addition ratio of 5% have more silt soil and sand than the soil samples with 7%. Finally, for the organic matter content, sawdust contains a lot of organic matter, so it's not difficult to understand that the organic matter content of adding ratio of 7.5% is greater than the value of 5%.

According to the experimental data, the comprehensive score $\beta$ of green soil of each group of samples were calculated, as shown in Table 5.

| Group | $v$ | $n$ | $n_z$ | pH | $w_s$ | $w_a$ | $\beta$ | $?$ |
|-------|-----|-----|-------|----|-------|-------|--------|-----|
| E₁    | 4   | 5   | 4     | 3  | 5     | 5     | 26     | √   |
| E₂    | 4   | 5   | 4     | 3  | 5     | 5     | 26     | √   |
| E₃    | 4   | 5   | 4     | 3  | 5     | 5     | 26     | √   |
| F₁    | 5   | 2   | 4     | 3  | 5     | 5     | 24     | √   |
| F₂    | 5   | 5   | 4     | 3  | 5     | 5     | 27     | √   |
| F₃    | 5   | 2   | 4     | 3  | 5     | 5     | 24     | √   |

The result shows that the scores of $\beta$ were same when the amount of sawdust was 5%. Meanwhile, the change of the proportion of medium sand had little effect on the improvement
effect. When the amount of sawdust was 7.5%, the change of the portion of medium sand made the total porosity of group F1 and group F3 exceed the upper limit, then reduced the improvement effect. Eventually, group F2 had the highest comprehensive index β value and the best soil quality.

The new green soil obtained on the basis of the evaluation criterion could meet the requirements in terms of permeability, soil fertility, pH and salt content, which has the good comprehensive performance. Finally, the new compound green soil was prepared according to silt soil: medium sand: sawdust = 72.5%: 20%: 7.5%.

3.3 Comparative Analysis of Properties of New Compound Greening Soil and Other Existing Soil

According to the mechanism of action of the sponge city, the effectiveness of the compound greening soil is mainly achieved through three characteristic parameters: penetration rate, maximum water holding capacity and field water holding capacity.

Firstly, the penetration rate could determine the speed at which rainwater seeps. The greater the penetration rate, the faster the rainwater seeps. Then, the maximum water holding capacity could determine the ability of green soil to store water. The greater the maximum water holding capacity, the stronger the ability of the green soil to store rainwater, and the more beneficial it is for rainwater control. Moreover, the difference between the maximum water holding capacity and field water holding capacity could determine the ability of the green soil to
retain rainwater. The greater the difference, the stronger the ability to retain rainwater, which could stagger the peak of rainwater runoff to avoid flooding.

To analyze the efficiency advantages of the new compound greening soil prepared in this research, it was compared that the three characteristic parameters of the new compound green soil with the existing soil.

The new composite greening soil was compared with the soil of the current Chenshan Botanical Garden [40], Shanghai urban green soils [41], as shown in Table 6.

Table 6. Comparison of Permeability and Water Holding Capacity

| Soil                          | Penetration rate (m/s) | Water holding capacity (g/kg) | Field water holding capacity (g/kg) | Difference (g/kg) | Bulk density (g/cm³) |
|-------------------------------|------------------------|-------------------------------|-------------------------------------|------------------|---------------------|
| Soil of Chenshan Botanical Garden | 0.98×10⁻⁶             | 336.25                        | 305.05                              | 31.20            | 1.42                |
| Green soil in Shanghai urban area | 0.97×10⁻⁶             | 379.46                        | 347.79                              | 31.67            | 1.31                |
| The new compound green soil   | 9.22×10⁻⁶             | 417.80                        | 316.50                              | 101.30           | 1.17                |

According to Table 6, the penetration rate of compound green soil was $9.22 \times 10^{-6}$ m/s, in contrast, the penetration rate of soil in Chenshan Botanical Garden and Shanghai urban area were $0.98 \times 10^{-6}$ m/s and $0.98 \times 10^{-6}$ m/s, respectively. Therefore, the penetration rate of the new compound green soil was significantly higher than the current penetration rate of the green soil in Shanghai, which ensures that rainwater could seep quickly. In addition, the difference between
maximum water holding capacity and field water holding capacity of the new compound greening soil (101.30 g/kg) was significantly higher than the current status of greening soil in Shanghai (31.20 g/kg), and the ability to accumulate and retain rainwater were significantly higher than the existing urban greening soil. Moreover, the new green soil meets the requirements of the sponge city for soil pH, fertility and salt content. However, the existing green soil in Shanghai has the defects such as low permeability and low organic matter content, which cannot meet the comprehensive performance requirements of the green soil in the sponge city.

Based on the comparison and analysis of permeation rate, the difference between maximum water holding capacity and field water holding capacity and other data, the new compound green soil has superior permeability and water holding capacity. Therefore, it means that the new compound soil can improve the control of rainwater, reduce runoff and play an important role in the construction of sponge cities.

3.4. Application Prospect of the Compound Greening Soil

Rainwater management measures and low-impact development technologies have been developed in developed countries such as Europe and the United States since the 1990s. In recent years, the Chinese government has issued a series of policies, plans, guidelines and other documents, proposing to vigorously develop sponge city construction. Moreover, many cities have begun to build sponge cities as pilot cities.

The design of the new compound greening soil serves the construction of the sponge city. Compared with the existing soil, the result shows the new greening soil not only meets the
technical requirements of the sponge city for soil, but also has excellent permeability and water
retention. Therefore, the soil can play a role in reducing runoff and increasing the annual total
runoff control rate, which could help strengthen the management of rainwater.

In the field of application, the new compound greening soil could be used for many low-
impact development measures for sponge cities such as green roofs, sunken green spaces,
biological retention facilities, infiltration ponds, rainwater wetlands, planting ditches and
vegetation buffers [42-44]. Therefore, the greening soil has many application fields and large
demand.

In terms of soil preparation, the compound greening soil is composed of silt soil, sand
and sawdust. As we all know, the raw materials are easily obtained, the economic cost is low,
and it is convenient for large-scale production.

Finally, the needs of society and urban development, the support of national policies,
outstanding self-efficiency and many application facilities all indicate that the prospects for the
application of new composite greening soils are considerable.

4. Conclusions

(1) To quickly evaluate the quality of green soil of green soil samples in sponge city, an
evaluation criterion of green soil was designed, and a comprehensive quantitative index $\beta$ was
defined.

(2) When the characteristics of permeability, water holding capacity, pH, aeration porosity and
fertility were comprehensively taken into account, a new type of compound greening soil was
deployed to solve the current existing greening soil that could not meet the requirements of sponge city construction. Its proportion is silt soil: medium sand: sawdust = 72.5%: 20%: 7.5%.

(3) Based on the comparison with other existing soils, the new compound green soil had apparent advantages under multi-angle analysis, and played a role in the construction of sponge cities with advantages such as high permeability and high water-holding capacity.

(4) The new greening soil has wide application fields and large demand. Meanwhile, the country has vigorously developed sponge cities, and the raw materials are cheap and easy to obtain. Therefore, the soil has considerable application prospects.
